SUBSECTION II RNA—Caliciviridae

Calicivirus (*Norovirus*, *Sapovirus*, *Vesivirus*, *Lagovirus*, *Nebovirus*)

169

Yalda C. Lucero • Miguel L. O’Ryan

Caliciviridae is a genetically diverse RNA virus family that currently includes five genera, *Norovirus*, *Sapovirus*, *Vesivirus*, *Lagovirus*, and *Nebovirus*.¹⁸² In addition, six unclassified caliciviruses have been described (Atlantic salmon calicivirus, Bavovirus, Nacovirus, Recovirus, Valovirus, and Secalivirus).^{87,128,165}

The first calicivirus-associated disease was described in animals in 1932, when outbreaks of a vesicular exanthema restricted to domestic pigs occurred in California and spread through the United States (vesicular exanthema of swine virus [VESV], prototype of the *Vesivirus* genus).^{159,160} Although diagnostic tools were not available to identify the causative agent, epidemiologic observations suggested an infective origin that was probably transmitted through contaminated food. Extensive programs of sterilization and restriction of consumption of food products for the pigs finally stopped the outbreaks in the 1950s.

In the 1970s, VESV strains were first visualized by electron microscopy; distinctive and unique features led to the name *calicivirus* (from “chalice,” due to the virion’s surface cup-shaped appearance).^{27,87}

Caliciviruses in humans were first recognized in 1972, when viral particles were isolated from stool samples of gastroenteritis patients involved in an outbreak affecting schoolchildren, teachers, and their household contacts in Norwalk, Ohio.^{1,97} Volunteer challenge studies proved the causal role of these round and rough-surfaced particles visualized by immune electron microscopy, which were named the Norwalk agent (prototype of the *Norovirus* genus). Many similar small, round-structured viruses (SRSVs) were described subsequently from outbreaks of gastroenteritis around the world. In parallel, investigators using electron microscopy to survey stool specimens from children with sporadic gastroenteritis visualized particles that did not have the appearance of SRSVs but instead were similar to the

animal caliciviruses previously identified.^{6,125} These “typical” caliciviruses occurred in a small percentage of sporadic diarrhea stool specimens and in a few outbreaks of gastroenteritis, including an outbreak in an orphanage in Sapporo, Japan (prototype of the *Sapovirus* genus). Biochemical and genomic sequencing analysis confirmed subsequently that the SRSVs (noroviruses) and human viruses with typical calicivirus morphologic features (sapoviruses) both belong to the *Caliciviridae* family.^{91,123}

In 1984, a highly fatal, highly contagious hepatitis syndrome was observed in European rabbits bred in China.⁵⁴ This syndrome spread some 7000 miles across Asia into Europe and reached Spain within 4 years, a dispersal rate of approximately 8 km/day. European rabbit populations experienced mortality rates exceeding 90% within 3 days of exposure. Typical calicivirus particles were visualized in infected rabbit livers, hence the term rabbit hemorrhagic disease virus was accrued (RHDV; prototype of the *Lagovirus* genus).¹³⁷

More recently, calicivirus isolates associated with gastroenteritis in bovines were recognized as a new genus, *Nebovirus*.^{80,98}

This summary illustrates the diversity of the ecologic relationships, whether animals and humans can be infected by a particular virus, and the broad spectrum of illness (from mild gastroenteritis to fatal hepatitis) associated with members of the *Caliciviridae* family. Next, we discuss the virologic, epidemiologic, pathogenic, and clinical features of caliciviruses, with emphasis on human infection.

VIROLOGIC FEATURES

The *Caliciviridae* family includes a heterogeneous group of nonenveloped, icosahedral viruses with a positive-sense, polyadenylated, single-stranded RNA genome approximately 7500 nucleotides in length. Cryoelectron microscopy and x-ray crystallography have resolved the three-dimensional structure of representative members of four of the five genera.^{36,147,183}

Typical calicivirus virion particles are 40 nm in diameter and have a $T = 3$ icosahedral symmetry, conformed by 90 dimers of the main structural protein, VP1 (Fig. 169.1).³⁶ VP1 is a 60-kDa protein that has two domains (S and P) linked by a hinge. The S domain is responsible for the shell structure of the capsid, and the P domain protrudes from the shell, generating spikes that denote the characteristic cuplike depressions that give name to this family.^{36,147} The genomic RNA is covered by the capsid and remains covalently attached by its 5′ end to the viral genome-linked protein (VPg).⁴⁶

The genomic organization among the calicivirus genera differ in the number and size of open-reading frames (ORFs), the presence of certain genes, and the need for posttranslational cleavage for gene product function (Fig. 169.2).^{30,51,91,127} The genomes of noroviruses and vesiviruses have three ORFs. ORF1 encodes a polyprotein cleaved by a viral protease during replication into a set of nonstructural proteins, including the RNA-dependent RNA polymerase (RdRp), the nucleoside triphosphatase, the protease, and the VPg; ORF2 encodes the main capsid protein; and ORF3 encodes a protein that appears to be a minor structural protein.^{79,91}

Some vesivirus strains differ from noroviruses in harboring a longer genome (e.g., Pan-1),¹⁵⁰ although this is not universal (e.g., feline calicivirus).³⁰ ORF2 and ORF3 genes of these genera are included in a subgenomic RNA that can be transcribed independently of the genomic RNA.^{91,150}

Sapoviruses, lagoviruses, and neboviruses have two ORFs. ORF1 is a fusion of the corresponding ORF1 and ORF2 of noroviruses and vesiviruses, whereas ORF2 encodes for a minor structural protein.^{138,139} An additional ORF, in another frame, at the 5′ end of the capsid gene is present in some strains of sapoviruses.¹³⁸

Calicivirus genomes have a highly conserved nontranscribed nucleotide sequence at the 5′ end of the whole genome and at the 5′ end of the capsid gene.¹⁰⁵ In addition, many caliciviruses have an overlap between the 3′ end of ORF1 and the 5′ end of the ORF2. Both features of genomic organization eventually favor recombination.²⁵

The description of distinct phylogenetic clades within *Caliciviridae* genera, and discrepancies of genotyping of some strains when RdRp and capsid sequences were analyzed independently, encouraged studies aimed at recognizing strains that might be natural recombinants within caliciviruses. Multiple naturally recombinant noroviruses, sapoviruses, and lagoviruses have been identified worldwide.^{7,56,78,118,145,180} Although this phenomenon has also been described in vesiviruses and neboviruses, it seems to be much more infrequent in these genera.^{50,83} Other than recognizing a recombinant genomic structure, the recombinants themselves seem unremarkable in terms of clinical consequences. Recombination may be a mechanism by which caliciviruses quickly escape host immunity, analogous to antigenic shifts among influenza viruses but by a different molecular mechanism. The recombination event could be recent or could have occurred in the remote past.

Generation of recombinants within caliciviruses requires certain biologic and molecular attributes. First, single cells are infected simultaneously by two calicivirus strains, in the absence of immune or molecular interference.

FIG. 169.1. X-ray structure of San Miguel sea lion virus (SMSV). (A) A sample region in the electron density map with modeled amino acid residues 175-189 (APAPTALATLATAST). (B) The x-ray structure of SMSV viewed along the icosahedral twofold axis (capsid protein subunits are shown as C α trace). Locations of a set of A/B and C/C dimers and icosahedral fivefold and threefold axes are denoted. The NTA (internal, not visible in this view), S domain, and P1 and P2 subdomains of the subunits are colored in green, blue, yellow, and orange, respectively. (C) A ribbon representation of the B subunit structure. The NTA (residues 163-200, green), S domain (residues 201-361, blue), and P1 (residues 362-413 and 590-703, yellow) and P2 (residues 414-589, orange) subdomains are indicated. (From Chen R, Neill JD, Estes MK, et al. X-ray structure of a native calicivirus: structural insights into antigenic diversity and host specificity. *Proc Natl Acad Sci U S A*. 2006;103[21]:8048-8053.)

FIG. 169.2. Genomic organization of calicivirus genera. The genome of *Norovirus* has three open-reading frames (ORFs) that in the 5' to 3' direction include a nonstructural polypeptide, the virion capsid gene, and a minor structural protein. The genomes of the other three genera differ from that of noroviruses in the length of the ORFs, including a unique gene at the 5' end of ORF1 in some vesiviruses and a post-translationally cleaved N terminus of the capsid protein in vesiviruses and sapoviruses. A subgenomic RNA beginning just 5' of ORF2 and continuing to the poly-A tail is synthesized during replication. Some sequence comparisons suggest that the longer ORF3 of *Norovirus* (and the comparable gene of *Sapovirus*) arose by intragenic recombination.

Outbreaks caused by multiple *Norovirus* strains and coinfection with different *Norovirus* strains occur.^{62,184,185} Second, the genomic structure of caliciviruses favors recombination, owing to overlapping regions between ORFs, conserved regions at the 5' end of the ORFs, and independent transcription with a high copy number of the subgenomic region. Finally, the calicivirus RdRp can recognize and process the highly conserved 5' end sequence of both ORF1 (for whole-genome transcription) and ORF2 (for subgenomic transcription) and can eventually switch from one RNA molecule to another.²⁵ The recognized recombinants may be a viable subset, among a larger set of recombination events occurring during replication.

Circulating caliciviruses are highly diverse.^{5,77,78} This diversity is explained not only by recombination, but also by frequent mutations, as for other RNA viruses, mostly by the high error rate in genomic transcription performed by the viral RdRp, which has no proofreading activity. According to sequence analysis of whole-genome and capsid regions, multiple genogroups, denoted by "G" plus a Roman numeral (e.g., genogroup II is denoted as GII), and genetic clades, named by Arabic numbers following the genogroup name (e.g., GII.4 for genotype 4 of genogroup II), of uncertain immunologic/biologic significance have been identified within each genus.

Even though no human calicivirus (*Norovirus* or *Sapovirus*) has been successfully cultivated to date, reverse genetic systems and recombinant technology developed to express capsid protein in different cell lines have allowed studies of virus assembly and characterization of antigenic properties of viral capsids.^{68,92,148,189,191} Enzyme-linked immunosorbent assays have been developed to detect viral antigens and antiviral antibodies directed against specific strains.^{88,90,92} An intense, clear reaction is usually evidenced for the specific strain, but frequent cross reactivity between genotypes and genogroups has also been reported.⁷⁷ Neutralization assays have not been performed for human calicivirus because of culture limitations; however, innovative receptor (histo-blood group antigen [HBGA]) blocking assays, and hemagglutination inhibition assays have demonstrated a high correlation between blocking/inhibiting antibody titers and protection against a specific strain.^{42,110,149}

EPIDEMIOLOGY

Human caliciviruses have worldwide distribution, and serologic studies indicate that infections by these agents occur commonly and early in life, with virtually all individuals having antibodies at 5 years of age.^{3,68,135,142}

Human caliciviruses are described as causing acute gastroenteritis mainly in two distinct situations: sporadic endemic cases affecting children younger than 5 years of age and elderly people, and outbreaks affecting individuals of all ages. *Norovirus* is the second leading cause of endemic acute diarrhea in children after rotavirus, with an increasing proportion after rotavirus vaccine introduction, causing 10% to 20% of overall cases and nearly 15% to 20% of diarrhea-associated hospitalizations.^{3,10,39,81,190,195} *Sapovirus* is comparatively less frequent, accounting for 1% to 12% of endemic gastroenteritis.^{113,126,157,168}

Noroviruses are the main cause of gastroenteritis outbreaks, associated mostly with contaminated water and food, particularly shellfish.^{75,76,174,186} Noroviruses account for approximately 50% of all outbreaks in countries with adequate sanitation and more than 90% of outbreaks for which no bacterial or parasitic cause can be found.^{76,174,186} Unlike noroviruses, sapoviruses are known primarily from sporadic cases of diarrhea in children, although outbreaks in closed populations do occur.^{106,174} Most human calicivirus outbreaks are recognized in close settings where common exposure occurs, such as nurseries, childcare centers, schools, hospitals, camps, hotels, and ships.^{10,76} In these outbreaks, in addition to the primary source (contaminated water or food), person-to-person spread also plays a significant role in prolonging outbreak duration. Long persistence of *Norovirus* gastroenteritis outbreaks has been described and has been associated with persistent asymptomatic excretion in food handlers, continual surface contamination, and reexposure to the same strain from contaminated foods.^{16,53} Primary attack rates in outbreaks frequently are high, near 30%, and secondary attack rates range from 5% to 30%.⁶⁶

Although high genetic and antigenic diversity have been described for human caliciviruses, mainly for *Norovirus*,^{60,77} a clear predominance of specific genotypes has been described and large changes in the relative prevalence of these genotypes have occurred during the past 40 years.¹⁰ For example, Norwalk virus, the prototype of GII.1 strains, and closely related strains appear to have been the predominant noroviruses in the 1970s in several regions studied.⁶⁹ Thereafter, Snow Mountain virus (the prototype of GII.2 strains) and related strains predominated, whereas strains within the clade that contains the prototype Norwalk virus (GI) were found infrequently (<5%).^{10,96,122} Beginning in the mid-1990s, GII.4 strains emerged and spread globally, currently representing more than 80% of noroviruses identified.^{45,60,108} Distribution of GII.4 lineages differs remarkably from region to region and/or over time, which could be at least partially explained by selective pressure due to population-acquired immunity.^{26,109,158} In the past 2 years the frequency of GII.17 genotype has markedly increased in some regions.^{44,158}

Both sporadic and outbreak-associated *Norovirus* infections are more frequent in autumn and winter, at least in regions with temperate climate.^{4,124,133} Exceptions to this trend are observed for particular transmission sources. Infections related to certain foods will occur when the foods are harvested and eaten fresh (fruit, salads, shellfish) or processed, shipped, and consumed later (frozen fruits, ice).^{12,116,155} Infections from exposure associated with recreation facilities, such as swimming pools, tend to have a summer seasonal predominance.^{154,194} In addition, contamination of water supplies occurs more frequently in a flooding situation resulting in the mixing of clear water and sewage and in situations associated with shellfish harvesting.^{13,29,102}

A distinct seasonal prevalence of *Sapovirus*-associated illness is not as apparent, but winter predominance is suggested based on several studies.^{49,143}

Vesiviruses include a large number of serotypes isolated from many different animal hosts, including pigs, cows, cats, dogs, sea lions, sea otters, walrus, whales, several snakes, pygmy chimpanzees, and gorillas, as well as a few isolates from humans.^{55,64,107,121,161,164} These viruses have a worldwide distribution in terrestrial and marine environments. Vesiviruses include at least 40 neutralization types (serotypes). The prevalence of these serotypes in different regions has had little study.

The prototype *Lagovirus* is the rabbit RHDV. Rabbits also are infected with *Vesivirus* strains, which may lead to confusion.¹²¹ RHDV has been epidemic in Asia and Europe since it was first recognized in China in 1984, and outbreaks in America and Australia have also been described.^{28,70} Disease spreads rapidly and appears to "leap" large distances in a short time. The ability of the virus to spread rapidly across large bodies of water (e.g., the English Channel) suggests that arthropods or other flying vectors have a role in transmission. Accidental and deliberate

importation and release have also been suspected.³⁵ RHDV infection is rabbit specific, and although this virus can bind HBGAs antigens, human disease has not been demonstrated.¹³⁶ In a food-associated outbreak in Mexico, antibody developed in one asymptomatic human.⁷⁰ Importantly, subclinical infection also occurred in some persons exposed to rabbits in Australia.⁴³ Zoo workers, rabbit breeders, and foresters have the largest occupational risk of RHDV exposure.

Nebovirus and its prototype strain Newbury-1 virus are bovine pathogens, causing acute gastroenteritis mainly in calves.^{98,139} Although the first report of these bovine pathogens was in the mid-1970s, they were not recognized as a different *Caliciviridae* genus until recently. *Neboviruses* have been detected in 3% to 10% of calves with diarrhea^{80,98} and have not yet been isolated in humans.

PATHOGENESIS

Human caliciviruses have not been successfully cultivated in cell lines to date, and animal models are still under development, a situation that has hindered elucidation of pathogenesis. Most of the information in this area comes from human volunteer studies, in vitro assays with virus-like proteins (VLPs), and animal models infected with murine, bovine norovirus, or porcine enteric calicivirus.⁷³ More recently, a probable breakthrough from Jones and colleagues is the development of an in vitro human *Norovirus* culture model using B cells in the presence of a commensal bacterium, *Enterobacter cloacae*.⁹⁴

Human volunteer studies performed in the 1970s suggested that some individuals seemed resistant to Norwalk virus infection after challenge even with high viral loads.^{10,144} The mechanism proposed for this differential risk was the absence or presence of HBGAs on digestive mucosa that could act as a host receptor. HBGAs are oligosaccharides present in human secretions and epithelia and are part of the innate immune system. The expression of HBGAs on mucosa is controlled by the activity of a fucosyl transferase-2 (FUT2), which is responsible for the synthesis of H antigen, the precursor of the A and B antigens. Individuals carrying an inactivating mutation of FUT2 do not express HBGAs on their epithelia, are eventually resistant to *Norovirus*, and are termed nonsecretors, whereas subjects with normal active FUT2 express these oligosaccharides and are called secretors. More recently, volunteer challenge studies, epidemiologic surveys, and in vitro assays have supported the role of these sugar structures in *Norovirus* virion attachment.^{23,37,84,119} A genogroup-specific HBGA-attachment pattern has been described in vitro that could be related to strain-specific susceptibility.⁸⁴

Secretor status does not completely explain the differences seen among infected and uninfected individuals for all *Norovirus* strains. Additional mechanisms are likely involved and remain an ongoing field of research.

The precise human calicivirus cell tropism is still under study, but evidence suggests infection of both immune cells (macrophages, dendritic cells, and B cells) and enterocytes.⁹⁹ According to current information, after ingestion, noroviruses reach the small intestine, where M cells can internalize viral particles and release them on lamina propria. From here, *Norovirus* may infect immune cells, triggering local inflammation and eventually translocation to mesenteric lymph nodes, leading to persistence.⁹⁹ Commensal bacteria, specifically those expressing HBGAs, are required for an efficient infection process.

Norovirus can be shed for up to 60 days in immunocompetent patients and for months to years in immunocompromised patients. Mechanisms of persistence are being researched. Evidence suggests that the ability of the strain to suppress CD8 T-cell response, antigenic changes to avoid recognition by antibodies, and suppression of IFN- γ by commensal bacteria may all contribute to *Norovirus* persistence.⁹⁹

Small bowel biopsy specimens obtained from *Norovirus*-infected volunteers in challenge studies mainly evaluating the prototype Norwalk virus have given some pathologic clues.⁸ Villous atrophy, epithelia disarrangement, crypt hyperplasia, cytoplasmic vacuolization, and lamina propria inflammatory infiltrate have been described in duodenal/jejunal biopsy specimens obtained from Norwalk virus-infected individuals. These morphologic changes have been evidenced both in symptomatic and asymptomatic infected subjects and as early as a few hours before the onset of clinical manifestations. No viral particle or specific cytopathic effects in enterocytes have been described. Histologic changes resolve after 2 weeks in immunocompetent individuals but could take months

in immunosuppressed patients.^{10,130} Sucrase, trehalase, and alkaline phosphatase activities from the intestinal brush border of symptomatic patients are decreased, inducing a transient malabsorptive state.²

The pathogenic features of *Sapovirus* infection in humans have not been determined and are presumed to be the same as those for *Norovirus*.

IMMUNOLOGY

The first barrier against human calicivirus is innate immunity, mainly represented by HBGA on the enterocyte surface, which acts as a virus receptor (see earlier discussion). Nonsecretor individuals lacking HBGA on their epithelia have a lower risk of *Norovirus* infection and *Norovirus*-associated gastroenteritis.^{10,23,112} HBGAs present in human breast milk can inhibit binding of noroviral virus-like particles (VLPs) to saliva and synthetic oligosaccharides in vitro; breast-fed infants from secretor mothers have a lower risk of gastroenteritis caused by *Norovirus* compared with other enteric pathogens.^{89,131}

Although human calicivirus infection triggers both humoral and cellular immune-acquired responses, infection by these agents can occur many times in the same individual and at any age. Protective acquired immunity to *Norovirus* seems to be complex and remains incompletely understood. Volunteer and clinical studies have demonstrated that 2 to 3 weeks after *Norovirus* infection, serum-specific antibodies can be detected and persist for many months.^{41,112} Adult individuals rechallenged by the same strain seems to be protected shortly after (6–14 weeks) the initial exposure but can be infected again when the exposure occurs 24 to 72 months after the first challenge.^{10,144} Cross reactivity has been described, but it seems to be restricted to strains of the same genogroups.¹¹¹ It has not been possible to correlate specific antibody titers with protection, and individuals with high serum and duodenal titers challenged with the same strain of *Norovirus* can be more susceptible than subjects who have lower titers or are seronegative.^{20,93} However, the viral infectious dose given to volunteers in these challenge studies was several times greater than naturally occurring infective doses and thus may not actually represent the phenomenon of natural immunity. Importantly, in children, there is evidence suggesting that repeated infections is common, but that a previous infection with a given genogroup confers protection against symptomatic reinfection when a child is reexposed to a virus from the same genogroup, as discussed later.¹⁴⁰

Viral neutralization assays have not been possible, owing to the lack of an adequate cell culture system. HBGA blocking assays and hemagglutination inhibition assays strongly suggest that natural infections are followed by the production of strain-specific protective antibodies.^{42,110}

Phase II trials with a virus-like particles vaccine have demonstrated modest protection against severe disease.⁹

CLINICAL MANIFESTATIONS

The incubation period after exposure to *Norovirus* ranges from 12 to 60 hours, with a mean of 24 hours.^{11,67} Stool excretion of *Norovirus* begins as early as 15 hours after the development of infection, peaks during the second day, and persists at least 7 days and up to 2 months.¹¹ Noroviruses also have been detected in vomitus, thus suggesting the possibility of spread by aerosol or dispersion of vomitus particles.^{33,120} Illness is usually characterized by a self-limited episode of nonbloody diarrhea, nausea, vomiting, and low fever, lasting 1 to 2 days in outbreak settings and 5 to 6 days in endemic cases.^{86,151} In children older than 1 year, vomiting predominates, whereas in infants and adults, diarrhea tends to predominate.^{10,66} This clinical presentation is indistinguishable from those of other enteric pathogens.

A wide disease spectrum ranging from asymptomatic excretion to severe gastroenteritis with dehydration requiring hospital admission can occur for human caliciviruses as for all enteric viruses; death from *Norovirus* illness rarely occurs.^{10,24,66,140} In general, human calicivirus gastroenteritis cases are milder than rotavirus cases, even though these agents may represent up to 20% of diarrhea-associated hospital admissions in children younger than 5 years of age.^{132,141} Chronic symptomatic infections have been described in immunocompromised individuals.^{59,153} Although the predominant feature of human calicivirus infections is by far gastrointestinal, some researchers have described viral RNA in serum samples, suggesting the possibility of occasional systemic infections.^{85,170} Febrile and nonfebrile seizures during *Norovirus* gastroenteritis have been described.^{34,38} Specific factors associated

with clinical severity have not been clearly identified; GII.4 *Norovirus* strains were associated with more severe cases in one study.²⁴

Sapovirus illnesses are also indistinguishable from those caused by other gastroenteritis pathogens, with a wide spectrum of severity, although most gastroenteritis cases are mild.^{48,63,126}

Vesiviruses cause a variety of severe illnesses in animals and are not currently considered a relevant human pathogen, with rare cases reported mainly in people with close exposure to animals. Nevertheless, a role in human disease cannot be excluded because anti-*Vesivirus* antibodies have been detected in blood donors and patients with asymptomatic elevation of aminotransferases.^{107,161} Smith and colleagues detected anti-*Vesivirus* antibodies in 12% of normal blood donors, at higher prevalence (21%) among otherwise normal donors with elevated serum levels of liver aminotransferases, and at highest prevalence (47%) among patients with hepatitis associated with blood exposures.¹⁶¹ Some individuals in the groups with normal and elevated aminotransferase levels also had *Vesivirus* RNA circulating in the blood. The exact clinical significance of this finding is still unclear.

One laboratory worker was infected with San Miguel sea lion virus (SMSV)-5 and experienced an influenza-like illness, followed during the next several days by viremia and a vesicular exanthem similar to that observed in the original pinniped host.¹⁶⁰ SMSV-5 was visualized in vesicular fluid by electron microscopy and was cultured from the lesions; the genome was amplified and sequenced. The worker also mounted a greater than fourfold serum neutralizing antibody response to SMSV-5. Biologists working with marine mammals had similar illnesses but were studied less intensively than was the laboratory worker.¹⁶³

Lagoviruses and neboviruses are not currently considered human pathogens.

DIFFERENTIAL DIAGNOSIS

Clinical presentations of acute sporadic gastroenteritis cases caused by human caliciviruses are indistinguishable from those of other viral and toxic causes of gastroenteritis. Individuals with calicivirus-associated infections tend to have less fever and more vomiting than those infected with other agents.^{10,141} Characteristic human calicivirus outbreaks are associated with a rapid onset of symptoms after contaminated water or food ingestion (24–48 hours of incubation), high primary and secondary attack rate, and a broad age range of affected individuals. The pattern of symptoms is a fairly good marker for calicivirus-associated outbreaks: a brief duration of illness, 2 to 3 days; vomiting as a prominent symptom in more than 50% of the outbreak cases; and cultures of freshly processed stool specimens negative for bacterial, parasitic, or fungal pathogens.^{13,66,74,92} When outbreaks have such characteristics, noroviruses will be detected in more than 80%.

DIAGNOSIS

Molecular and immunologically based techniques have been developed for human calicivirus detection in both clinical and environmental samples.

Real-time quantitative reverse transcription–polymerase chain reaction (RT-PCR) assays directed against a small region in the 5′ end of ORF2 (a highly conserved region) are currently the most sensitive test for *Norovirus* and *Sapovirus* detection in both stool and environmental samples,^{95,177,179,178} and can be applied in endemic and outbreak gastroenteritis cases. Cautious interpretation has to be given to detection of very low viral loads, because asymptomatic excretion is common.^{24,140} This assay discriminates between genogroups (GI and GII) but not between subtypes, which may make epidemiologic studies and tracking of a potential infectious source in outbreaks difficult.¹⁷⁸ Technical modifications have been developed for simultaneous screening of a high number of samples and simultaneous detection of multiple enteric pathogens.^{58,82,166}

Conventional RT-PCR was the main diagnostic technique until the mid-2000s, after which it was largely replaced by the highly sensitive and faster real-time assay; currently its main application is for nucleic acid amplification for DNA sequencing and genotyping.^{179,178} The gold standard for *Norovirus* genotyping is full-capsid sequencing; however, this procedure is very time consuming and technically difficult, making it impractical in clinical and epidemiologic settings.¹⁹³ In addition, recombination in the ORF1–ORF2 junction region is common. Currently

a dual-nomenclature system has been proposed using small fragment sequences of both the RdRp region in ORF1 and a segment of VP1 in ORF2.^{104,181} This system allows better discrimination between strains, with only slightly less differentiation when compared with full-capsid sequencing and detection of recombinant variants, which is the reason why it is more practical for clinical sample analysis.

To date, nine genotypes in GI, 22 in GII, two in GIII, two in GIV, one in GV, two in GVI, and one in the tentative new GVII have been recognized for *Norovirus*.¹⁸¹ Human infection can be produced by GI, GII, and GIV *Norovirus*.

Enzyme immunoassays (EIAs) for stool antigen detection have been developed, and commercial kits are currently available.³¹ Among the advantages of these methods are their high specificity, lower cost, and lower requirements for skilled personnel and complex instruments³²; the disadvantage is their lower sensitivity due to a high antigenic diversity of human caliciviruses and a low stool viral load that can be under the threshold of detection. Compared with RT-PCR, the sensitivity of new-generation commercial EIA kits ranged from 61% to 80%, and specificity has ranged from 92% to 100%.^{65,100} Because of the modest sensitivity of these commercial kits, they are not currently recommended for *Norovirus* detection in sporadic gastroenteritis cases. However, given their ease of use and rapid results, these methods have been recommended for screening of multiple stool samples obtained from gastroenteritis outbreaks; negative results do not exclude *Norovirus* etiology, and molecular tests should be performed in outbreak situations if *Norovirus* is highly probable.

Immunochromatographic rapid tests have also been developed. The advantages of these methods are their potential use as point-of-care tests to provide rapid results. However, their low sensitivity (near 70%) currently limits their clinical application.⁶⁵

TREATMENT AND PREVENTION

Nonspecific Measures

Children with diarrhea are more likely than children without diarrhea to be excreting enteric viruses, including caliciviruses. Infection with noroviruses requires a very small inoculum, on the order of 100 particles, which favors transmission in closed settings and through fomites.^{32,52,115} For children in care settings as well as for hospitalized children, a few infection control measures are likely to reduce the spread of infection. Such measures include personnel training in hygiene and isolation procedures, cleanliness of surfaces (with sodium hypochlorite solution or 70% ethanol) and in food preparation, exclusion of ill care providers, adequate hand washing, and exclusion or cohorting of ill children.^{32,52} Laboratory workers exposed to caliciviruses should be aware of the risk for acquiring infection.

Specific Measures

No specific treatment for calicivirus infection has been established. Feline interferon and ribavirin inhibit the replication of feline calicivirus (a *Vesivirus*) in feline cell lines.^{129,146} Morpholino antisense oligomers blocked production of *Vesivirus* and murine *Norovirus* virions cultivated in cell lines and inhibited the protein expression of Norwalk virus in replicon-bearing cells.^{22,167} These antisense compounds have potential for prophylaxis and treatment of illness, although their potential future clinical use in humans seems highly unlikely.¹⁶² More recently, a nucleoside analogue, 2′-C-MeC, showed significant *in vitro* activity against a GII *Norovirus* prototype and could be further explored for human use.⁴⁰ Use of HBGA receptor blocking molecules has also been postulated as a possible therapeutic strategy for the future.¹³⁴ Improved understanding of the pathobiology and life cycle of *Norovirus*, and advances in the identification of targets related with viral and host factors, in a new replicon system, in a small animal model for preclinical evaluation, and in high-resolution x-ray crystal structures provide some optimism regarding novel therapeutic and prophylactic molecules for *Norovirus*.⁶¹

Vaccines for feline calicivirus and RHDV indicated that this prevention method could work for other caliciviruses. The development of human vaccine candidates has focused on noroviruses, with substantial advances during the past decade. *Norovirus* vaccines incorporating an immunogen-expressed capsid protein that self-assembles into VLPs have been the candidates most extensively studied.^{8,14,15,71,169} More recently, viral particles formed specifically by the P domain of the capsid protein (P particles) and viral vectors incorporating *Norovirus* capsid genes have been studied

TABLE 169.1 Vaccine Candidates Against Norovirus

Antigens in the Vaccine	Stage of Development	Comments	References
Norovirus VLPs GI.1 and GII.4	Clinical: phase I and II in adults completed, advancing to phase III trials in adults and children	Baculovirus expression system of VLPs. First delivered by intranasal route and currently developed for intramuscular administration. Immunogenic, well tolerated, moderate protection against severe disease after challenge.	18, 176, 196
Norovirus VLPs GI.1	Clinical: phase I in adults completed (data not published)	Recombinant vaccine using a replication-defective adenovirus 5 vector expressing GI.1 VP1 for oral administration.	197
Norovirus VLPs GI.1, GI.3, GII.4, and GII.12	Preclinical: in vitro and BALB/c mouse model	Baculovirus expression system, intramuscular administration. Triggers serum HBGA blocking antibodies.	198
Norovirus VLPs GI.3 and GII.4 and rotavirus rVP6	Preclinical: immunogenic in BALB/c mouse model	Baculovirus expression system, intramuscular administration. Norovirus VLPs associated with rVP6 rotavirus nanotubes elicited higher titers of anti-norovirus antibodies with higher blocking activity against binding to HBGAs than free VLPs alone.	199, 200
Norovirus VLPs GII.4 and enterovirus 71	Preclinical: immunogenic in BALB/c mouse model	Baculovirus expression system, intraperitoneal administration. Elicits production of HBGA blocking antibodies against GII.4 norovirus and neutralizing antibodies against enterovirus 71.	201
Norovirus P-particles	Preclinical: immunogenic in BALB/c mouse model and gnotobiotic pigs	High expression yield in <i>E. coli</i> system. Intranasal administration.	57, 103, 173
Norovirus GII.4 P-particle enhanced by adjuvant FlaB	Preclinical: immunogenic in BALB/c mice model	Expression in <i>E. coli</i> system. Administered by intranasal and sublingual route. Higher levels of response by intranasal administration. FlaB induces systemic and mucosal Th1 and Th2 responses.	202
Norovirus, hepatitis E, and astrovirus P-particles	Preclinical: immunogenic in a BALB/c mouse model	Expression of recombinant fusion protein including P domain of the three viruses. Intranasal administration. Elicits a significant increase in titers of antibodies against the three viruses. High blocking activity against norovirus binding to HBGAs.	203
Virus replicon particles including norovirus P domain	Preclinical: replication in vitro model and immunogenic in BALB/c mouse model	Replication in eukaryotic cell lines and inoculation in mice by intranasal administration. Elicits a Th1 predominant response. Higher levels of seric IgG than baculovirus-expressed VLPs.	101, 114, 204

HBGA, Histo–blood group antigen; VLP, virus-like particle.

Modified from Lucero Y, Vidal R, O’Ryan GM. Norovirus vaccines under development. *Vaccine*. 2017. Epub ahead of print.

as potential vaccine candidates. Candidate vaccines in different stages of development are shown in Table 169.1.

A safe and effective *Norovirus* vaccine could play a significant role in reducing the impact of large gastroenteritis outbreaks occurring in specific settings in which large groups of individuals are compromised. Army personnel (especially those allocated to large ships), foreign aid workers, cruise ship workers, and residents of elder care facilities are examples of populations that could benefit from *Norovirus* disease prevention.⁵² More importantly, a vaccine targeted for infants, following the age strategy used for rotavirus, could have a significant impact in further reducing the toll from death, hospitalization, and medical visits associated with childhood endemic gastroenteritis. Current epidemiologic data indicate that an effective vaccine could reduce emergency department visits or hospitalizations associated with gastroenteritis by up to 20%.¹⁴¹

Barriers to *Norovirus* vaccine development have been to with the perception that immunity is short term and strain specific and that the significant genetic/antigenic variability may impair the effectiveness of a vaccine including a limited number of antigenic variants. The concept of short-term immunity was obtained from challenge studies in adults^{144,187}; the situation in children may be different. A cohort study in infants from Chile indicates that *Norovirus* infections and reinfections are very common and caused largely by GII strains, but that symptomatic reinfections are uncommon during the first 3 years of life. Not a single case of a symptomatic GII infection was detected.¹⁴⁰ Thus, similar to rotavirus, it is possible that a GII *Norovirus* vaccine would be protective against symptomatic disease during the first critical 3 years of life and probably less protective against asymptomatic and mild infections. This vaccine outcome would be of unquestionable epidemiologic benefit worldwide.

The proof of concept for *Norovirus* vaccines came from a *Norovirus* VLP formulated in a powder form, adjuvanted with monophosphoryl lipid A (MPL) and chitosan, for intranasal use.⁸ In a placebo-controlled trial including 90 adults receiving two doses of a Norwalk virus G1.1, VLP or placebo demonstrated a 70% immunoglobulin A antibody

response in vaccine recipients. A Norwalk virus challenge caused gastroenteritis in 69% of placebo recipients and in 37% of vaccinated individuals ($P = .006$), whereas infection occurred in 82% and 61%, respectively ($P = .05$). Local and systemic side effects were similar among vaccinees and placebo recipients at about 70% each. Corporate decisions led to a change in vaccine strategy, moving to an intramuscular formulation that includes two VLPs, GI.1 and GII.4, because of the epidemiologic significance of both *Norovirus* types and the low level of cross reactivity between them. A first study concluded that 50 µg per antigen dose seemed optimal when administered with MPL in terms of an adequate balance between immunogenicity and side effects.¹⁷³ A GII.4 challenge study in adults using this candidate, although not optimal because of a low induction of disease in placebo recipients, suggested protective efficacy ranging from 47% to 100% with increasing disease severity.¹⁸ This vaccine candidate is in rapid stage of development and intended to move to phase III trials in adults, children, and infants during 2017–18.

P-particle–based vaccines that include the protruding P domain of the VP1 protein induce both humoral and cellular immune responses in mice.⁵⁷ The advantages of this approach are lower cost of production, higher yield, and the possibility of combining different antigens such as rotavirus, influenza virus, hepatitis A, astrovirus, and HIV^{171,188,192} in a parenteral vaccination strategy, although antigen combination also seems feasible for VLPs, at least with rotavirus VP6 antigen.²¹

Viral vectors incorporating *Norovirus* capsid genes have included¹⁷ vesicular stomatitis virus,¹¹⁷ avian paramyxovirus, avian “Newcastle virus,”¹⁰¹ adenovirus,⁷² and Venezuelan equine encephalitis virus.¹⁷ The adenovirus recombinant candidate has moved to phase I clinical trials but the others are still in the preclinical development stage.

PROGNOSIS

Understanding of the features of calicivirus infection in humans has increased rapidly since 1990, when molecular tools for studying the viruses

became available. The availability of refined diagnostic techniques has significantly increased our understanding of calicivirus-associated disease. Gastroenteritis that is mostly mild to moderate, but also can be severe, is the sole recognized disease associated with these viruses in humans. Severe cases have been reported mostly in infants, older adults, young healthy men under physical stress (e.g., military personnel), and immunocompromised patients.^{47,59,140,153} Disease is usually short-lived, with the exception of infection in immunocompromised individuals, including children with solid-organ transplants, in whom it can cause prolonged diarrhea and viral shedding for months.^{59,152,153} Severe chronic diarrhea can also occur in children with stem cell transplantation.¹⁵³ Deaths associated with *Norovirus* infections have been reported in adults with hematopoietic stem cell transplantation.¹⁵⁶ Nevertheless, these complications are rare, and most infected individuals fully recover within 1 week.

Hepatitis E virus (HEV) is a virus that was characterized just 20 years ago but has likely been infecting humans for hundreds of years. New information about its animal reservoirs, epidemiology, and molecular biology is constantly becoming available. Natural disasters and regional warfare constantly highlight HEV as an agent that causes epidemics in areas where sanitation and public health systems have broken down. New developments offer hope that protection using vaccine will soon become a reality. This chapter is a summary of the discoveries so far with emphasis on the impact of children infected with HEV.

HISTORY AND DISCOVERY OF VIRUS

As methods to detect hepatitis A and B virus as the major causes of fecal-oral and blood-borne hepatitis, respectively, became more reliable in the 1970s, more cases were being classified as “non-A, non-B hepatitis.” Investigations in regions of South Asia looked at epidemic and endemic cases of acute hepatitis.^{48,86,184} Case patients all had a clinical course that was very similar to hepatitis A virus (HAV) despite a remote history of HAV, and testing for other causes of viral hepatitis was negative. Many believed that a distinct enteric viral agent was the cause of these cases.

The first evidence of this came when Balayan and colleagues used stool extracts from infected humans orally administered to a human volunteer known to be HAV immune.¹⁸ Classic hepatitis symptoms ensued, and stool from the infected volunteer was used to reinfect cynomolgus macaques. Electron microscopy of stool samples from the asymptomatic and early symptomatic phase showed virus-like particles (VLP) approximately 30 nm in diameter that banded at 1.35 g/cm³ on a CsCl gradient.^{28,29} The VLPs showed no cytopathic effect when passaged in tissue culture, and mice inoculated with the VLPs showed no signs of disease.¹⁸

The field experienced a major advance after the reverse transcription–polymerase chain reaction (RT-PCR) identification of hepatitis C virus in 1989.³⁴ Similar methods were used to determine the nature of the non-A, non-B enteric virus.¹⁴¹ Reyes and colleagues constructed cDNA clones from infected bile that subsequently hybridized with RNA from infected animal and human liver, as well as isolates from five distinct geographic outbreaks. Sequence analysis revealed the presence of an RNA-dependent RNA polymerase, a common feature of plus-strand RNA viruses. Northern blot hybridization identified a 7.4-kB molecule present only in homogenates from infected liver samples. The agent was pronounced “hepatitis E virus,” and further efforts by the same group cloned and sequenced HEV during the subsequent year.¹⁵⁹

MICROBIOLOGY AND GENOME ORGANIZATION

HEV is a plus-sense RNA virus with a genome size of approximately 7200 base pairs.^{159,186} Initial cloning of the Burma strain revealed the presence of three overlapping open-reading frames (ORFs).^{159,172} ORF1 is approximately 5000 base pairs in length and encodes for the nonstructural proteins.^{93,159} ORF2 begins 37 base pairs downstream from the ORF1 stop codon and codes for the viral capsid.¹⁵⁹ ORF3 is only 369 base pairs and overlaps both ORF1 and ORF2. The viral RNA contains a short 5′ untranslated region (UTR) of approximately 27 base pairs and a 3′ UTR of approximately 65 base pairs.¹⁵⁹ The genome has a 7-methyl cap at the 5′ UTR and a poly-A tail of approximately 150 to 200 bases.⁷⁶ The organization of the genome is represented in Fig. 170.1.

Initial comparative genomic analysis deduced the likely functions of the ORF1 nonstructural regions.⁹³ They include the methyltransferase “capping” motif (~amino acids 56–240), papain-like cysteine protease

(~amino acids 433–592), RNA helicase (~amino acids 960–1204), and the RNA-dependent RNA polymerase (RdRp) (~amino acids 1207–1693). Details of ORF1 processing are limited, but recent data examining ORF1 using a baculovirus system showed extensive cysteine protease processing.^{9,128,146} The enzymatic activities of the methyltransferase and RdRp have been demonstrated in independent studies.^{7,105}

ORF2 codes for the viral capsid protein.¹⁵⁹ Specific studies of the ORF2 have shown a membrane export signal sequence (amino acids 1–36) at its extreme N terminus, several glycosylation sites, and multiple smaller processed forms.^{72,142,159,193} ORF2 has dimerization sites and can assemble into VLPs when the first 110 amino acids are deleted.^{100,101,189} Studies have shown that ORF2 dimers can encapsidate and deliver exogenous HEV RNA to naïve cells.¹²⁹

The role of ORF3 appears to be multifaceted. A key function of the protein appears to be in mediating viral egress from cells.¹⁹⁰ ORF3 deletion mutant viruses can replicate RNA, but this RNA is almost entirely intracellular. Specific studies have shown that a specific proline-containing motif within ORF3 is responsible for interacting with cellular Tsg101, which has also been shown to interact with several other viruses.^{47,84,122} Other effects include interaction with the MAPK/ERK pathway, ORF2, binding and self-association.^{83,94,177,178} Recent studies have shown that ORF3 also mediates the evasion of interferon responses in A549 cells.⁴⁴

Viral Structure and Stability

Electron micrographs from fecal samples of patients and animals infected with HEV show the virus to be approximately 27 to 30 nm in diameter.^{18,28,29}

Ultrastructural studies of HEV have involved ORF2 expression, and the empty VLPs produced are slightly smaller than the infectious HEV virus.^{101,189} The VLPs assemble from 30 dimers to form a spiky hollow sphere.¹⁸⁹ Although the empty VLP shares much similarity with the native virion in appearance, further confirmation is lacking until a tissue culture system is available. Similar to hepatitis A virus, HEV appears to exist in both an enveloped and nonenveloped form, depending on the setting of isolation.^{137,192}

Several strains of HEV are almost completely heat inactivated by 60°C, compared to 66°C for HAV,⁴⁶ with some interstrain variability. Virus containing stocks have been stable at extreme cold temperatures with several freeze-thaw cycles.⁴⁶ Based on persistent HEV infections during an outbreak from water containing chlorine concentrations of 0.3 to 0.6 mg/L, HEV may be resistant to chlorine inactivation.⁶⁰

Viral Life Cycle

For many years, HEV did not grow in tissue culture conditions, so detailed information regarding viral structure and life cycle were limited.⁴⁸ Studies have now shown evidence of HEV replication in primary macaque hepatocyte cultures and cell lines for many species known to become infected with HEV.^{149,160,161} When in vitro transcribed RNA from a full-length cDNA clone was transfected into liver cell lines, viral proteins could be detected and the culture supernatant could be used to infect a rhesus monkey.¹²⁸ The cross-species cell-culture experiments discussed earlier discovered that a recombinant strain replicated in tissue culture to high levels and formed the basis of a subgenomic replicon.¹⁴⁸ Studies with this system have demonstrated that sofosbuvir, ribavirin, and mycophenolate can inhibit replication, whereas cyclosporine can promote replication.^{41,181} HEV clinical strains isolated from feces and blood can replicate to high titers in the PLC/PRF/5 liver cell line and the A549 lung cell line.¹⁶² Antibodies from patient serum, whether it was IgM, long after convalescence, or against heterotypic stains, were able to

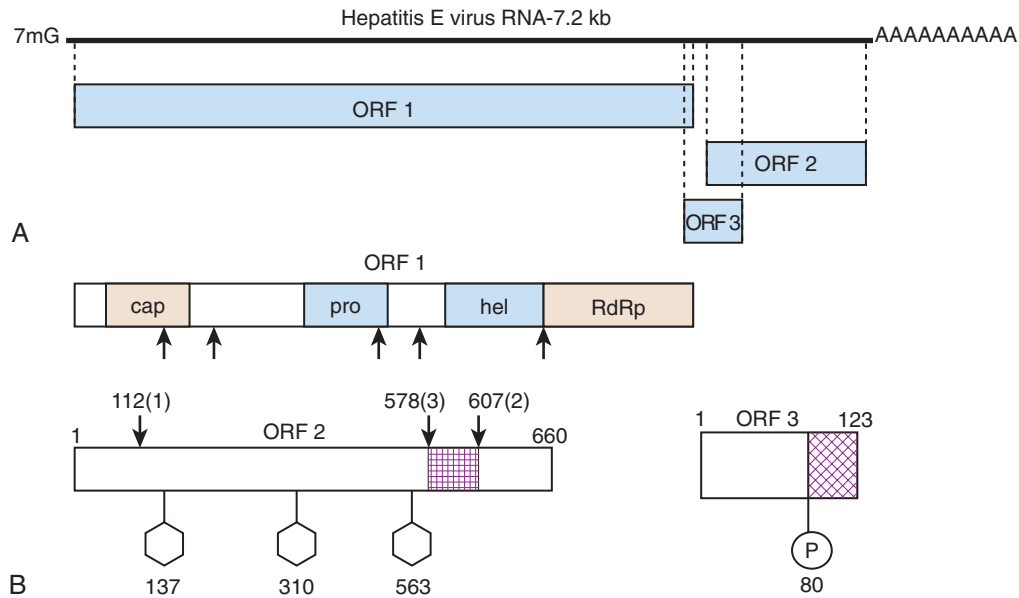

FIG. 170.1 Hepatitis E virus (HEV) genome and open-reading frames. (A) HEV genome overview. The HEV RNA is single stranded and features three overlapping reading frames: ORF1, ORF2, and ORF3. (B) Individual features of the HEV ORFs. ORF1 contains the nonstructural protein domains (*shaded*), which include the methyltransferase (*cap*), cysteine protease (*pro*), helicase (*hel*), and RNA-dependent RNA polymerase (*RdRp*). Proposed cleavage sites are illustrated with the *bold arrows* at their approximate locations. ORF2 is the structural capsid protein, which is 660 amino acids in length. Cleavage sites are indicated by the *bold arrows* at their determined amino acid positions. Glycosylation sites are represented with *polygons* at their determined amino acid positions. The domain of ORF2 that has been determined to be the neutralization epitope is represented by the *cross-hatched box*. ORF3 is the smallest protein, and its phosphorylation site is represented by the *circle labeled P*. The domain responsible for dimerization is represented by the *diagonal hatched box*.

neutralize HEV in cell culture, demonstrating the validity and utility of the system.

Although the specific receptor for HEV is still unclear, much progress has been made in recent years. HEV VLPs enter the cell via clathrin-mediated endocytosis in a process that also involves dynamin-2, cholesterol, and asialoglycoprotein receptor.^{66,81,196} After the virus gains access to the cell, it uncoats and translates its RNA in order to produce enough nonstructural proteins to begin the transcription/replication process.¹²⁸ A genomic and 2-kb subgenomic RNA are produced, as well as a negative-strand replication template.^{56,161} Studies using real-time PCR coupled with live cell imaging demonstrated a peak of negative-strand RNA at 8 hours postinfection, followed by a decline.¹⁸⁰ Positive strand RNA peaked at 14 hours postinfection. With the accumulation of transcripts, structural proteins begin to accumulate, as well as more plus-sense daughter RNA. ORF2 gets cleaved, dimerizes, and associates with the HEV RNA to form new virions.¹⁵⁶ These accumulated virions are subsequently released by a mechanism that involves the endosomal secretory pathways and TSG101.^{85,122}

Viral Genetics

There are four main genotypes of HEV.¹⁸⁶ Genotype 1 is distributed throughout the world from South Asia to North Africa. Genotype 2 is most common in Mexico but has been isolated in certain countries in Africa. Genotypes 3 and 4 are the zoonotic strains of HEV that are found in swine and humans from developed western countries and China, respectively. Genotypes 1 and 2 are approximately 70% to 80% homologous, whereas genotype 3 strains are more removed from genotype 2 strains (25–50% homology).¹¹⁴ Generally, genotypes 1 and 2 are closer to each other and genotypes 3 and 4 are closer to each other.¹⁰⁴ This makes sense because genotypes 1 and 2 are responsible for endemic and epidemic diseases, whereas genotypes 3 and 4 are responsible for zoonotic disease and sporadic human cases.

There is only one serotype of HEV.^{112,115,145,186} There is some evidence that HEV develops quasispecies during epidemics that allow for adaptation within individual hosts.⁵⁷

Taxonomy and Classification

Prior to the characterization of HEV, it was proposed to be closely aligned with the calicivirus family based on physical characteristics.^{18,159} After the full cloning of the virus and the identification of the three ORFs, the virus was formally classified with the caliciviruses.

Subsequent work showed that HEV shared several characteristics with rubella virus and other “alpha-like” viruses.⁹³ An analysis performed comparing the helicase and polymerase regions of HEV with members from the Caliciviridae, Picornaviridae, and Togaviridae families showed significant divergence.²² The ICTV decided to separate HEV from the Caliciviridae family based on these findings and leave it unclassified.⁵⁸

In 2014, after incorporating new genomic sequences of the new Hepeviridae family, two new genera were created: *Piscihepevirus* (which include those isolates that infect fish) and *Orthohepevirus* (which include those isolates that infect birds and mammals).¹³⁶ Within the *Orthohepevirus* are four types, and type A is the one containing HEV isolates that infect humans, swine, boar, and camels.

EPIDEMIOLOGY

Endemic Hepatitis E Virus

HEV is endemic in areas of the developing world where sanitation and clean water are not readily available. South/Southeast Asia and North Africa experience endemic disease, as well as regions of Mexico and South America. Large epidemics of HEV occur in these endemic countries related to widespread contamination of water after natural disasters. Cases of HEV outside these areas were inevitably traced back to some travel to one of these areas. Global estimates of the burden of HEV in endemic countries arrived at 20 million incident infections in 2005, with more than 3 million symptomatic cases and 70,000 deaths.¹⁴⁰ Sixty percent of these cases occur in South and East Asia, with another 14% in North Africa.

Most of the seroprevalence studies performed in endemic countries have shown that unlike HAV, children are not universally infected with

HEV early in life. Children in the first decade have anti-HEV+ rates of approximately 3% to 4%,^{10,15} and the peak of HEV seropositivity is the second and third decades of life. However, studies from regions of Egypt and northern regions of India demonstrate a pattern that is similar to that of HAV, with 60% to 70% of children under 10 years being anti-HEV+.^{6,50,111} Egypt has much higher prevalence than neighboring Israel, whereas southern and central India have anti-HEV rates much lower than the northern regions just described.^{10,82,119} A study of children from Moscow had HEV seroprevalence rates that fell in between those of most other studies.¹ Explanations for these regional differences are lacking. Table 170.1 is a summary of HEV seroprevalence studies performed in children from different parts of the world.*

One of the Egyptian seroprevalence research groups performed a follow-up study to examine seroconversion and estimated the incidence of HEV.¹⁵⁴ Of the 919 villagers who were anti-HEV-negative at the beginning of the study, 34 seroconverted over 10 months, or an incidence of 41.6/1000PY for this group.

Studies of sporadic acute hepatitis in endemic areas indicate the burden of HEV disease in those countries. Studies examining children presenting with acute hepatitis symptoms in Egypt and Sudan show that HEV is either the leading cause or second leading cause in children.^{45,69,70} A similar study from India showed that, although HEV was the second leading cause after HAV of acute hepatitis requiring admission to a children's hospital, it caused a slightly higher percentage of acute liver failure.¹³³ One study found that HAV/HEV infections led to worse outcomes in acute liver failure, but others have not substantiated those findings.^{16,107}

There have also been several studies from endemic areas specifically designed to examine the differences in HAV and HEV infections.^{31,144} The results of these studies have shown that HAV disease peaks earlier in life than HEV, and that although the clinical symptoms of acute hepatitis are very similar, the hepatic dysfunction from HEV tends to peak earlier in the illness and may take longer to resolve. Because the peaks of HAV and HEV seroprevalence and disease in endemic countries do not overlap, some believe that HAV disease somehow either protects against or interferes with HEV infection.¹⁵⁷ No specific proof of this hypothesis is available currently.

Although the reservoir for HEV is not known, the detection of HEV from various sewage samples combined with patients with prolonged viremia make it likely that the virus can exist in these environments to sustain its transmission cycle.^{124,131,179}

Epidemic Hepatitis E Virus

HEV epidemics are often related to events that cause disruption of sanitary conditions (war, earthquakes, flooding, etc.). War-associated epidemics among the refugees from the Darfur region of Sudan and Iraq in 2004 illustrate the nature of HEV epidemic circulation.^{25,54,60,182}

In a refugee camp in Western Sudan, there were more than 2600 reported cases of HEV among the estimated 78,000 residents in the second half of 2004.^{25,60} Of the total cases, almost 10% required hospitalization, and of the hospitalized cases, 45 (17.8%) died.²⁵ The bulk of the mortality was among pregnant women, 19 of 45 (42.2%), and in fact, the sentinel cases for the HEV epidemic were two pregnant women who died in July 2004. The overall mortality for the epidemic was 1.7%. There were a total of 1133 pregnant women in the refugee camp, of whom 220 reported jaundice (19.4% attack rate), and the mortality rate was 8.2%.

The main source of water for the camp was unchlorinated ground-water pumped in through pipelines or surface water with chlorine added that refugees could access.⁶⁰ In the analysis of those patients with symptomatic HEV infection and those with asymptomatic infection, patients aged 15 to 45 years had a higher attack rate and more symptomatic infections (4.3% and 71% respectively) compared to the group aged less than 15 years (2.4% and 22%). Intrafamilial spread of HEV previously did not appear to play a significant role during epidemic conditions.^{5,12} However, a large outbreak in northern Uganda with more

than 3000 cases demonstrated in households with two or more cases that they were more likely to have had contact with people likely to have been infected with HEV.¹⁶⁵ All tested water and zoonotic sources were negative for HEV, thus suggesting person-to-person spread.

Zoonotic Hepatitis E Virus

As more widespread serologic studies were performed to assess rates of anti-HEV seropositivity, cases with no identifiable travel risks were discovered in developed countries with no known endemic HEV activity.^{33,110,167} Many of the cases had heavy animal exposures, most commonly to swine. This led researchers to investigate the possibility that HEV was in fact a zoonosis, and that either direct animal contact or ingestion of raw or undercooked meat could produce HEV infection. Meng and colleagues conducted a multiphase study to determine if swine were infected with HEV and to isolate the virus.¹¹⁶ They performed ELISAs on multiple swine herds and found the majority to be anti-HEV+ and that the seroprevalence increased with age. They followed newborn piglets, monitored for seroconversion, and demonstrated concurrent histologic hepatitis and viremia by RT-PCR. In a follow-up study, serum from the infected piglets was used to successfully infect pathogen-free experimental pigs.¹¹³ Pigs could not be infected with human strains of HEV. Rhesus monkeys and chimpanzees, both human surrogates, were successfully infected with the swine HEV.¹¹⁴ An isolate of HEV from the United States that was genetically similar to the swine HEV successfully infected pathogen-free pigs, thus proving that swine HEV could infect both pigs and humans and was the likely cause of sporadic cases of HEV in the United States and other developed countries. It has now been established that HEV genotypes 3 and 4 are the strains most frequently isolated from animals that are found in nonendemic HEV cases from industrialized countries.³⁸

There are many animal species likely infected with HEV. Among those described are swine, deer, chickens, camels, rodents, and cats.^{64,65,67,75,126,185} Of note, avian HEV, which has been demonstrated as the cause of hepatosplenomegaly syndrome in chickens, shares only 50% to 60% homology with human and swine HEV and has not been shown to be able to infect nonhuman primates.^{65,68}

Vertical and Breast Milk Transmission

Studies done on pregnant women with HEV have also shown that vertical transmission does occur. The small studies performed show that HEV is likely transmitted at high rates, and the infants can be severely affected or die before or soon after birth.^{89,90,151} Recent studies have shown that HEV RNA and protein can be identified in placental tissue from symptomatic mother-infant pairs.²⁶ This high mortality during pregnancy with HEV infection and vertical transmission has been recapitulated in a rabbit model.¹⁸⁸ Offering some insight into a possible mechanism for this severe illness, HEV infected A549 cells supplemented with serum from pregnant patients produced higher levels of OR2 and secreted lower levels of IFN- β .²⁴

There have been limited studies on breast milk transmission. HEV RNA and anti-HEV antibody have been detected in colostrum components, but at significantly lower titers compared to serum.³³ No cases of HEV transmission in the infants were definitively linked to breast milk; however, mothers with advanced liver disease were not allowed or able to breast-feed in this study. In short, no recommendations exist to contraindicate breast-feeding in this population aside from those mothers with severe disease.

Other Modes of Transmission

Cases have been reported of HEV linked with transfusion of contaminated blood. Donors were in the presymptomatic viremic phase, and recipients of those blood products developed symptoms of acute hepatitis with a shorter incubation period than patients infected via the usual fecal-oral route.^{13,14,27,91}

Consumption of undercooked wild game meat has been implicated in HEV infections. Several cases have been reported of acute HEV after consumption of uncooked or undercooked deer, wild boar meat, camel meat, and camel milk.^{96,97,163,164} An outbreak in France was traced to consumption of uncooked pig liver sausage.³⁷ Comparison of HEV RNA sequences from index cases and sausages revealed 99.4% identity,

leading to a new package label recommending the sausage be cooked prior to eating.

PATHOGENESIS AND IMMUNITY

Pathogenesis

The details of pathogenesis in HEV infection are largely unknown. After an individual consumes HEV-contaminated water or food, it is unknown how the virus infects enterocytes and spreads from the intestine to the liver. Studies in swine show replicative HEV RNA present in colon, small intestine, lymph nodes, tonsils, and liver as early as 3 days postinfection.¹⁸³

Evidence of HEV replication within the liver as detected by HEV antigen is apparent by 7 days postinfection. At its peak, HEV antigens can be detected in 70% to 90% of hepatocytes before the onset of symptoms and then drops off rapidly.⁴ Viremia is detectable in serum, stool, and bile prior to the onset of symptoms.^{32,103,169} Anti-HEV appears at the same time as the histologic signs of inflammation.³⁵ Similar to HAV, disease is likely caused by the immune response to the virus and not the virus itself.⁴

The majority of the information regarding progression and pathogenesis comes from HEV inoculation of animals.^{18,103,169,173} These studies usually involved intravenous administration, with an incubation period from administration to viremia of approximately 3 weeks, approximately 1 week less on average than humans. HEV RNA can be detected in serum, stool, and bile 1 week before clinical symptoms become apparent.

In the HEV volunteer studies, the patients developed constitutional symptoms at approximately 4 weeks after administration.^{18,32} Specific symptoms and the biochemical abnormalities of hepatitis developed 1 week later. Early studies showed that viral particles appeared in stool with the onset of symptoms and continued through the peak hepatitis symptoms, and antibody was present at the only time they tested, 1 week after the peak hepatitis symptoms.¹⁸ Subsequent studies using RT-PCR showed that HEV RNA was present in serum earlier than in stool samples and was present from 1 week prior to 2 weeks after symptoms had begun.³² Peak alanine aminotransferase (ALT) elevations corresponded with peak symptoms, and symptoms lasted between 30 and 80 days. HEV IgG persisted well beyond the study endpoint.³²

The presence of HEV RNA in stool and serum can vary significantly from patient to patient.³ In 20 patients diagnosed with sporadic HEV, HEV RNA appeared in serum at days 4 to 7 after the onset of symptoms in 89% of patients tested and persisted beyond day 22 in 21%. HEV RNA in stool samples was present in 73% of patients at days 8 to 14 after symptoms, peaking slightly later than serum HEV RNA, and persisted beyond day 22 in 13%. A subset of patients will have HEV RNA in serum and stool for up to 120 days.¹²⁴ It is possible that these patients with prolonged shedding may serve as a reservoir for spread of HEV to the environment.

A summary of the clinical progression of HEV infection is graphically represented in Fig. 170.2.

Immunity

HEV antibody appears with the onset of symptoms and after the peak of viremia. IgM appears just ahead of IgG (see Fig. 170.2). HEV IgA appears at the same time as IgM and appears to persist slightly about 1 month longer after infection than IgM.^{158,168} ORF2 is the dominant immunogen across all types of HEV, although antibodies to ORF3 can be detected in patients.^{59,69,70,109,191} A more detailed discussion of neutralizing antibodies can be found in the vaccine subsection.

Some studies of patients after infection have shown that HEV IgG responses wane quickly after infection, whereas others show a more durable antibody response.⁵⁵ The waning of IgG levels observed forms the basis for the theory that susceptible adults accumulate to form the vulnerable population during HEV outbreaks.

Cellular immunity to HEV plays a role in eradication of infection and persistence of viral immunity.¹²³ Specific studies comparing patients with resolved acute HEV and transplant patients with resolved and chronic HEV have demonstrated a role for broad polyspecific T-cell

FIG. 170.2 Course of hepatitis E virus (HEV) infection with approximate times after HEV exposure. In volunteer and animal experiments, prodromal symptoms will appear approximately 3 weeks after infection, which precedes the symptoms of hepatitis by about 1 week. The hepatitis symptoms can last 4 to 6 weeks on average, with significant variation. Serum alanine aminotransferase (ALT) peaks with the onset of hepatitis symptoms. HEV RNA can be detected in either stool or serum approximately 3 weeks after infection with the onset of the prodrome and can be detected for a 1- to 3-week duration, with some patients experiencing prolonged viremia. HEV immunoglobulin (Ig)M and IgG appear in concert with the onset of symptoms and after the peak of HEV RNA. IgM peaks slightly earlier than IgG and can taper quickly, with some disappearing by 3 months. IgG peaks later and lasts for several months after infection.

responses against the virus.¹⁵⁵ Regulatory T cells appear to increase in number during acute HEV infection.¹⁷¹

CLINICAL MANIFESTATIONS

The signs and symptoms of acute HEV infection are indistinguishable from those seen with HAV.^{4,31,70,144} A prodromal illness consisting of malaise, anorexia, nausea, abdominal pain, fever, myalgia, and headache precedes the findings of jaundice, hepatomegaly, and serum transaminase elevations.

One study examining children after a common source exposure provides insight into the manifestations of HEV in this group. Twenty students from a private school in urban North India were exposed to HEV while on a camping trip.¹⁷ The exact source was never identified, but investigators were able to monitor the children for signs and symptoms of HEV infection as well as serologic and virologic confirmation of infection. The clinical symptoms are summarized in Fig. 170.3. Seventeen of the 20 children developed clinical illness (85%), but only

Symptom

FIG. 170.3 Symptoms observed in children after a common-source exposure to hepatitis E virus. Jaundice was seen in only 50% of patients overall, and 15% were completely asymptomatic. (From Arora NK, Panda SK, Nanda SK, et al. Hepatitis E infection in children: study of an outbreak. *J Gastroenterol Hepatol.* 1999;14:572–577.)

10 children developed symptoms of acute hepatitis. The other seven remained anicteric, with symptoms of malaise, nausea, abdominal pain, and headache. The children with jaundice had a different incubation period (25–38 days; median, 33 days) compared to the children without jaundice (22–95 days; median, 27 days). HEV IgM was found in all patients. HEV RNA was found in 11 children, including one of the children who never developed any symptoms. Because this study is one of the few to have a point source of exposure, it is difficult to know if the very high rate of infection is due to the younger age of the patients, the strain of the virus, or the nature of the exposure.

Rates of fulminant hepatic failure and mortality from HEV are estimated to be approximately 1% to 4%. Studies from endemic areas suggest that the rate may be higher in children, but those data have not been widely substantiated.¹³² The rate is closer to 15% to 50% in patients with preexisting liver diseases and compensated cirrhosis, whether due to chronic hepatitis B or C or other metabolic liver disease.¹³⁹

Although it was previously thought that HEV only caused acute disease, many studies have demonstrated that chronic HEV can occur in immunocompromised and/or transplant patients.^{61,79,118} This has been observed in children, with outcomes including cirrhosis and death.^{62,63}

Pregnant women are highly vulnerable to HEV infection.^{39,88} It was recognized before HEV was fully characterized that infected pregnant women had high rates of fulminant liver failure and mortality rates of 20% or higher.⁹² One study from India of pregnant women with acute hepatitis demonstrated not only that HEV caused fulminant hepatitis and death more frequently, but also that it was associated with many obstetric complications (antepartum and postpartum hemorrhage, premature rupture of membranes, intrauterine fetal death) and poor

fetal outcomes (preterm delivery, stillbirths) when compared with other forms of viral hepatitis.¹³⁰ This feature of HEV is not restricted to a particular region or genotype, as illustrated by the Darfur outbreaks. The mechanism for severe disease in these women is unknown, although one study showed an increased Th2 cytokine bias in peripheral blood mononuclear cells (PBMCs) from pregnant HEV-infected patients that could allow for a dysregulated inflammatory response.^{25,127} Pregnant women with HEV have significantly longer periods of viremia than nonpregnant counterparts, also supporting the idea of a muted or dysfunctional immune response.²¹

Extrahepatic manifestations of HEV have been reported, but they are uncommon. Pancreatitis can occur shortly after the onset of acute hepatitis symptoms.^{73,106,117} Several reports have described patients with significant hemolysis with glucose-6-phosphate dehydrogenase (G6PD) deficiency associated with acute HEV infection.^{2,194} Neurologic manifestations described include transverse myelitis, Bell palsy, and Guillain-Barré syndrome.^{42,43,77,108,152} All of these manifestations resolve spontaneously in conjunction with the hepatitis. It is not clear whether these are a result of direct viral effects or an immune-mediated phenomenon. It is interesting that most of the extrahepatic manifestations been reported in children.

DIAGNOSTIC TESTING

Serology

Antibody confirmation is the most widely available method used to diagnose HEV infection. Enzyme-linked immunosorbent assay (ELISA) for both IgG and IgM can be obtained at many reference laboratories. The ORF2 capsid protein is the most common antigen used to detect antibody.¹⁷⁴ Some studies have shown that inclusion of the other ORFs can increase the specificity and positive predictive value of the test. A few studies have shown that HEV IgA may perform better than IgM-based testing.^{158,168} This needs to be confirmed in larger studies.

A comparison of different HEV ELISA kits during an epidemic in Indonesia found that the sensitivity of the tests was much better in symptomatic patients than in asymptomatic ones (72–91% vs. 39–51%, respectively).¹²⁰ Also, the Walter Reed kits for IgG and IgM performed better than the GeneLabs and Abbott IgG tests. Testing of normal healthy controls that were HEV PCR negative showed that the serologic testing had high specificity, again with the Walter Reed tests performing best. The caveat of the study is that the GeneLabs IgM kit was an older version of the test, and the limitations of the assay may not apply to the newer kit.

A new rapid immunochromatographic assay showed promising results when it was evaluated for use in resource poor countries to diagnose acute HEV.¹²¹ Using 25 μ L of serum or 35 μ L of whole blood applied to the test strip and a 15-minute incubation period, the kit had a sensitivity of 93% and a specificity of 99.7%.

Polymerase Chain Reaction

RT-PCR for HEV RNA can be performed within the first month of illness on either serum or stool.³ The testing is less available commercially and is likely conducted in research or select public health labs. Several recent studies have shown that real-time PCR testing may allow more rapid and sensitive detection of HEV RNA with the additional benefits of detecting multiple HEV genotypes and the ability to test environmental samples in addition to clinical samples.^{49,74}

Electron Microscopy

HEV has also been visualized in stool samples from patients using electron microscopy.^{18,153} In general, these methods incorporate HEV antibody to adsorb intact virus to increase the likelihood of detection. Again, this testing is not generally available.

DISEASE PREVENTION AND VACCINE CANDIDATES

Disease Avoidance

Practical measures can be taken to reduce the risk of HEV infection when traveling to endemic regions.³⁰ Consumption of only boiled or

bottled water, avoidance of ice, eating fruits that can be peeled, and eating only well-cooked foods are all recommended measures.

Specific consideration should be made for pregnant women and patients with chronic liver disease to avoid travel to areas endemic for HEV or regions experiencing HEV outbreaks.

Antibody Preparations

There are no available antibody preparations that can be used as pre- or postexposure prophylaxis for HEV. There have been small studies showing successful passive immunization in animals.¹⁷⁵ There have also been studies with immune serum globulin in endemic areas with mixed effects.^{11,87} These studies are all small, and the antibody preparations were of varying amounts given at varying times, so definitive conclusions about the role of antibody cannot be made.

Therapies

Most patients do not need therapy for acute HEV infection. Development of therapies for HEV is not likely to be effective for the simple reason that the peak of viral activity is usually prior to and along with the onset of symptoms. The patients with prolonged viremia are not necessarily the sickest patients; they are often asymptomatic. However, patients with less common manifestations might benefit if therapies existed. Ribavirin has been used with success in patients with fulminant infection, although it is not clear if the drug was critical in the recovery of the patient.⁵² Ribavirin has also emerged as the primary option for immunocompromised patients with chronic HEV and appears to function by inducing lethal mutagenesis in the viral genome.^{78,170}

Vaccine Candidates and Future Therapies

Early vaccine studies used cynomolgus monkeys actively immunized with a recombinant ORF2 protein. Subjects were protected after challenge with homologous virus compared to passively immunized or control animals.¹⁷⁵

Work to identify neutralizing antibody showed that the epitopes recognized were in the terminal region of ORF2, amino acids 578 to 607.¹⁴⁵ These antibodies were protective of HEV infection when incubated with HEV prior to administration to monkeys. This epitope is present within the 56-kDa form of the capsid protein.

A recombinant 56-kDa ORF2 vaccine protected rhesus monkeys challenged with HEV 1 month after a two-dose series was complete.^{135,176}

Repeat challenge at 6 months and 1 year showed protection against hepatitis in 75%, which increased to 100% in animals given a third dose of vaccine 1 month prior to challenge.¹⁹⁵ Postexposure vaccination did not prevent HEV infection.

Subsequent phase I testing in humans induced anti-HEV titers ≥ 40 U/mL in 88% of vaccinees after three doses.¹⁴³ There were only few minor local reactions and no significant adverse events. Based on these early trials, a large human field trial was completed in Nepal in 2001. Two thousand seronegative soldiers were randomized to receive three doses over 6 months of the recombinant HEV vaccine or placebo.¹⁴⁷ The subjects were followed for signs and symptoms of acute hepatitis for 2.5 years. There were 69 total cases of acute HEV, 66 in the placebo group and three in the vaccine group, an efficacy of 95.5% in subjects receiving three doses of vaccine. The intent to treat analysis showed an efficacy of 88.5%. The vaccine was well tolerated, with local pain at the injection site being the most frequent complaint.

Another version of recombinant vaccine against hepatitis E produced in bacterial cells has moved through preclinical testing with promising results. A large phase III trial in China with more than 90,000 subjects showed that the vaccine was highly protective, with rates between 95% and 100%.¹⁹⁸ Only one case of HEV was observed in a subject who received only one dose of vaccine, compared to 22 in the placebo group. Follow-up studies have demonstrated durable vaccine-induced protection after almost 5 years.¹⁹⁷ A subsequent analysis of women in the study who became pregnant after enrollment demonstrated no associated pregnancy complications or fetal morbidity/mortality.¹⁸⁷ Antibody levels among those women who received study vaccine were comparable to those of nonpregnant counterparts in the study. These findings certainly raise the possibility that an HEV vaccine may become available to protect pregnant women in endemic areas. There have been some calls for

public health authorities to consider using this vaccine during worldwide outbreaks to reduce overall morbidity and mortality from HEV.¹²⁵

Alternative vaccine strategies being investigated include VLPs given orally to induce local and systemic immunity. Mice immunized with HEV VLPs in increasing amounts developed serum IgG and IgM responses at 2 to 4 weeks postimmunization.⁹⁹ Mice given the higher inoculums (50 and 100 μ g) also developed fecal IgA responses. Subsequent challenge experiments in cynomolgus macaques showed that oral immunization with VLPs not only produced serum and fecal antibody but protected the animals from intravenous challenge with native HEV strains.⁹⁸ DNA vaccines have shown encouraging initial results as well. Macaques given a DNA plasmid encoding for the HEV ORF2 using the gene gun technique developed significant anti-HEV IgG within 4 months of vaccination, and vaccinated animals were protected against challenge with infectious HEV, whereas control animals developed clinical disease.⁸⁰

SUMMARY

Many important developments have been made in our understanding of HEV, including the ability to conduct meaningful studies with in vitro systems and effective therapies for chronic infection. Some fundamental questions of virus entry and pathogenesis still linger, as well as why certain patients are highly susceptible to severe HEV disease while others are not. The nature of the differences in the epidemiology and clinical manifestations of HEV in children also needs to be studied further. The existence of an efficacious vaccine with durable immunity raises the question of how hard public health authorities and nongovernmental organizations will work to protect those most vulnerable to HEV.

SUBSECTION III RNA—Reoviridae

Reoviruses

171

James D. Cherry

Reoviruses are ubiquitous in nature, but their role in human disease is vague. After reoviruses were classified in 1959, numerous reports noted their association with human disease.^{46,75,79,86} Since that time, these viruses have been evaluated extensively in laboratory animal studies, but few cases of human disease have been reported during the last 5 decades.

HISTORY

On the basis of its cytopathic effect in monkey kidney tissue culture and its recovery from stool specimens at a time of enterovirus surveillance, the first recovered reovirus was designated ECHO virus type 10.^{18,103} This virus and four similar strains were recovered in 1954 from the stools of healthy children in Cincinnati and Mexico.⁶⁸⁻⁷⁰ By 1959, researchers were aware that ECHO 10 viral strains appeared to have many characteristics that were different from those of enteroviruses, such as large size and unique cytopathic effect, and they were withdrawn from this grouping. The term *reovirus* was chosen to stress the association of these agents with both the respiratory (*r*) and enteric (*e*) tracts. The *o* for orphan was retained in the designation. In the early 1960s, reoviral infections were noted in association with human illness.^{16,31,36,46,75,76,79,80,113}

PROPERTIES

Reoviruses are members of the family Reoviridae.^{19,13,60} This family has numerous double-stranded RNA viruses that infect mammals, birds, reptiles, fish, mollusks, insects, plants, and arthropods. The family Reoviridae contain 15 genera, which are divided into two groups based on their particle morphology. One subfamily (Sedoreovirinae) contains six genera, and three of these (*Orbivirus*, *Rotavirus*, and *Seadornavirus*) are presented in Chapters 172 and 173. The other subfamily (Spinareovirinae) contains nine genera, one of which (*Orthoreovirus*) is discussed in this chapter. Orthoreoviruses have a turtle-like protein that projects from the innermost capsid layer. Sedoreovirinae do not have this turtle-like protein. Orthoreoviruses commonly are called simply reoviruses. Historically, three serotypes of orthoreoviruses were noted to cause infection in humans. All mammalian reoviruses are related by a common group-specific, complement-fixing antigen.^{13,82} Three distinct human serotypes can be identified by neutralization or hemagglutination inhibition.^{73,80}

Reovirus particles are composed of an inner protein shell (core) with a diameter of 60 nm that is surrounded by an outer protein shell (outer capsid) measuring 81 nm in diameter.¹³ The outer capsid has icosahedral symmetry and is composed of 92 to 180 hexagonal and pentagonal subunits (capsomers). The genome of orthoreoviruses has a total size of approximately 23,500 base pairs with 10 gene segments:

three large (L1, L2, L3), three medium (M1, M2, M3), and four small (S1, S2, S3, S4). These genes encode 12 proteins. The outer capsid comprises four proteins: σ -1, σ -3, λ -2, and μ -1. The σ -1 protein is the reovirus cell-attachment protein against which serotype-specific neutralizing antibodies are developed. This protein also is the hemagglutinin. The reovirus receptor is the junctional adhesion molecule 1 (JAM1).^{20,99} The σ -3 protein binds double-stranded RNA and is sensitive to protease degradation. It is a zinc metalloprotein that has effects on translation. The λ -2 protein is important in particle assembly and μ -1 in cell penetration.

The inner capsid is composed of four proteins: λ -3, λ -1, μ -2, and σ -2. The λ -3 protein is an RNA-dependent RNA polymerase. The λ -1 protein is a zinc metalloprotein that binds RNA. The μ -2 protein binds RNA, and σ -2 binds double-stranded RNA.

The four nonstructural proteins are μ -NS, μ -NSC, σ -1s, and σ -NS. The μ -NS protein is a core-binding protein, and σ -NS binds single-stranded RNA. The roles of μ -NSC and σ -1s are unknown.

Reoviruses are moderately heat stable. The half-life at 56°C (132.8°F) of a type 3 strain is 1.6 minutes; at 37°C (98.6°F), it is approximately 2.5 hours. Reoviruses are inactivated by visible light in the presence of heterocyclic dyes. They are inactivated by ultraviolet light but are more resistant to this treatment than are RNA viruses with single-stranded nucleic acid. Reoviruses are stable through a wide pH range and also as aerosols, particularly when the relative humidity is high. They are relatively resistant to 3% formaldehyde solution, 1% hydrogen peroxide, and 1% phenol but are inactivated completely by 70% ethyl alcohol at room temperature for 1 hour. Brief exposure to 70% ethanol is ineffective in disinfecting reoviruses, but brief exposure to 95% ethanol or sodium hypochlorite is effective.

Reoviruses replicate with a cytopathic effect in a large number of tissue culture systems of both primate and other animal origins. For recovery from clinical material, monkey kidney tissue culture is satisfactory. Cytopathic effect is enhanced in rolled in contrast to stationary cultures.⁴⁵ Infected cells develop characteristic cytoplasmic inclusions that contain double-stranded RNA, virus-specific proteins, and complete and incomplete viral particles. All three serotypes agglutinate human erythrocytes, and this virus-cell interaction is stable in a wide temperature and pH range.

Of all viruses that naturally infect humans, reoviruses have the broadest host range. They have been recovered from natural infections in cattle, chimpanzees, monkeys, mice, dogs, turkeys, sheep, pigs, chickens, and cats.^{11,26,28,51,53,54,73,77,83,108,109} In addition, hemagglutination-inhibiting and neutralizing antibodies to one or more of the three reoviral serotypes have been found in the serum of rabbits, horses, trout, guinea pigs, antelopes, zebras, warthogs, bats, wallabies, quokkas, kangaroos, and several genera of New World monkeys.^{59,73,74,77,80,82,93,95}

Keywords

Reovirus
Reoviridae
Sedoreovirinae
Spinareovirinae
Upper respiratory tract illness
Pneumonia
Mild diarrhea
Exanthem

Because of their widespread prevalence in nature and the ease of causing infection in laboratory animals, reoviruses have been used widely in pathogenicity studies. The following unique illnesses have been observed: diabetes mellitus in mice; hydrocephalus in hamsters, ferrets, rats, and mice; encephalitis in mice; chronic infection with runting in mice; myocarditis in mice; chronic obstructive jaundice associated with choledochal obliteration in mice; and lymphomas in mice with chronic infection.^{13,33,39,49,50,62,63,67,88,92,94}

EPIDEMIOLOGY

The serologic data presented in the preceding section of this chapter demonstrate that reoviruses are prevalent infectious agents in the animal world. Similarly, surveys of sera collected from humans indicate worldwide human infection.^{4,5,6,22,37,44,46,47,66,81,85,100,101,105} The occurrence in nature of identical viruses in many different animals and humans leads to consideration of possible transmission from species to species. Chua and associates⁸⁻¹⁰ and other investigators^{21,89,90,110} present data suggesting that reoviruses associated with human respiratory infections were of fruit bat origin. In addition, Ouattara and colleagues⁶⁴ have noted a reovirus type 2 swine reovirus reassortant associated with encephalitis.

Reoviruses are recovered frequently from sewage.^{17,35,42,48,52,61} In San Diego prior to 1972, reoviruses were recovered more consistently than has any other virus throughout the year from sewage.¹⁷ This finding suggests that reoviral infection was endemic in humans in the San Diego area.

The type 2 hemagglutination-inhibiting antibody prevalence pattern by age in sera collected in Boston from 1959 to 1962 is presented in Table 171.1. Antibody is transmitted transplacentally to the newborn. During the first year of life, this acquired antibody wanes, after which antibody prevalence increases with increasing age. Approximately 50% of school-aged children have hemagglutination-inhibiting antibody titers to type 2 reovirus of 1:20 or greater; approximately 80% of adults have similar titers. Two more recent studies have shown a similar prevalence of antibody to reovirus type 3.^{87,100}

The method of transmission of reoviruses is unknown. However, because they are recovered most frequently from the feces, the primary spread probably from person to person is by the fecal-oral route, similar to that of enteroviruses. Because the reoviruses are stable in aerosols and because respiratory illness has been associated with reovirus infections, the respiratory route is an additional possibility. The method of spread of fruit bat (flying foxes) reoviruses to humans is not known.

CLINICAL MANIFESTATIONS

The role of reoviral infections in human disease is far from clear. In most instances, virologic or serologic evidence of reoviral infection has

been a sporadic finding in human illness, so that cause and effect are difficult to establish. However, in volunteer studies in young adults, infection resulted in clinical illness.^{31,74,78}

The prevalence of antibody to all three reoviral types in humans and the frequency of reovirus isolation from human sewage indicate that human infection is a common occurrence, but the relative paucity of virus recovered during studies of community disease suggests that most infections are inapparent or associated with trivial illness.

Upper Respiratory Tract Illness

In the winter of 1957, Rosen and colleagues^{75,79} noted an outbreak of infection with reovirus type 1 in nursery children in a welfare institution. Illness was noted in 16 of 22 infected children and was characterized by low-grade fever (rectal temperatures from 38.1°C to 38.6°C [100.6°F to 101.5°F]), rhinorrhea, and pharyngitis. The average duration of fever was 2.2 days; in nine children, the duration was only 1 day. Three children had diarrhea, and three had mild otitis media. In another study conducted at the same institution during the winter of 1955 to 1956, four children with reovirus type 3 infection and illness were noted.^{76,80} One child had a temperature of 38.9°C (102°F), coryza, and tonsillitis; another child had fever (temperature of 38.2°C [100.8°F]), cough, and diarrhea; and two children had only coryza. During another reovirus type 3 outbreak in the fall of 1957, all six infected infants had symptoms. Five children had mild fever, five had coryza, and four had diarrhea. Pharyngitis was not observed in any of the infected children.

Other sporadic instances of similar mild upper respiratory tract illnesses have been described.^{12,27,31,96,97} In volunteer trials in young adults, reovirus type 1 infection was associated with malaise, rhinorrhea, cough, sneezing, pharyngitis, and headache in some subjects in one study,^{74,78} and coldlike illness was observed in 37% of subjects in another trial.³¹ In both volunteer studies and natural infection, mild diarrhea occurred with the upper respiratory tract illness.

In three separate investigations, Chua and coworkers⁸⁻¹⁰ noted acute influenza-like illnesses in four adult patients. The reoviruses in these four cases were of fruit bat origin, and in one instance evidence of human-to-human transmission was found.

Pneumonia

Tillotson and Lerner¹⁰⁴ described a 5-year-old girl who had extensive pneumonia and died after 15 days of illness. This child initially had fever, cough, rhinorrhea, and a generalized maculopapular rash. When admitted to the hospital on the tenth day of illness, the child was cyanotic and in marked respiratory distress; rash was no longer present, but mild pharyngitis and conjunctivitis were. A chest radiograph revealed diffuse confluent pneumonia, and reovirus type 3 was recovered from the lungs, adrenals, liver, spleen, kidney, a lymph node, heart, brain, and blood.

Joske and associates³⁶ described a 10-month-old girl who died after having a respiratory illness of 4 days' duration. A reovirus type 1 was recovered from the stool and brain of this child, and postmortem study revealed interstitial pneumonia, myocarditis, hepatitis, and encephalitis. El-Rai and Evans¹⁶ reported the case of an 18-year-old man who had fever (temperature of 39.4°C [103°F]), nausea, vomiting, cough, and patchy pneumonia. He had serologic evidence of infection with reovirus type 1. Pneumonia has been noted in another child with reovirus type 3 infection.⁹⁶

Gastrointestinal Manifestations

Mild diarrhea has been noted both in association with upper respiratory tract illness and as an isolated event.^{69,70,74-76,78-80,83} Because reovirus type 3 consistently produces steatorrhea in mice, this clinical manifestation has been sought in illnesses of children and noted in six.^{36,96} Three patients with hepatitis and encephalitis have been described.³⁶ Zalan and associates¹¹³ have noted two patients in whom abdominal pain and cramps were prominent.

In 1980, Bangaru and associates¹ reported the similarity of induced hepatobiliary injury caused by reovirus type 3 infection in mice and biliary atresia in human infants. Subsequent to this observation, Glaser and associates²³ and Morecki and colleagues^{23,57,58} looked for an association

From Lerner AM, Cherry JD, Klein JO, et al. Infections with reoviruses. *N Engl J Med*. 1962;267:947–952.

between reovirus type 3 infection and biliary atresia in humans. In their first report, they found that 17 of 25 patients (68%) with biliary atresia had antibodies (indirect immunofluorescent antibody technique) to reovirus type 3, whereas similar antibodies were recovered in only three of 37 control sera.⁵⁷ In a second study, they found that 62% of babies with extrahepatic biliary atresia and 52% of infants with idiopathic neonatal hepatitis had antibodies to reovirus type 3; only 12% of control children had similar antibodies.²³ In an ultrastructural and immunocytochemical study, they found evidence of reovirus type 3 in the porta hepatis of an infant with extrahepatic biliary atresia.⁵⁸

Using similar serologic techniques, Dussaix and associates¹⁴ were unable to find any relationship between reovirus type 3 antibody and either biliary atresia or neonatal hepatitis. They found reovirus type 3 antibody in sera from 45% of infants with biliary atresia, 50% of infants with neonatal hepatitis, and 50% of control infants. Minuk and colleagues⁵⁶ found no association between reovirus type 3 infection and idiopathic cholestatic liver disease in adults. Brown and colleagues⁷ reported a relatively large study of reovirus type 3 infection and extrahepatic biliary atresia and neonatal hepatitis. They interpreted their data as demonstrating no correlation between the virus and the illnesses studied. However, the geometric mean antibody value in the combined biliary atresia and neonatal hepatitis groups was significantly higher than that of the control group. Richardson and associates⁷² reported a study in which they examined the percentage of immunoglobulin (Ig)G, IgA, and IgM serum antibodies to reovirus type 3 in 40 infants with extrahepatic biliary atresia, 59 infants with neonatal hepatitis, 61 infants with cholestatic liver disease with causes other than extrahepatic biliary atresia or neonatal hepatitis, and 138 control infants with no liver disease. They found no difference in the prevalence of IgG and IgA antibodies between the groups with liver disease and the control subjects. They did, however, note a greater prevalence of IgM antibody in each of the groups with liver disease, in contrast to the rate in the control group. However, this increased prevalence of IgM antibody could be the result of false-positive titers as a result of the liver disease rather than evidence of recent or ongoing infection. Steele and associates,⁹⁸ using a reverse transcriptase-mediated polymerase chain reaction (RT-PCR), found no evidence of reovirus type 3 in preserved tissues from infants with cholestatic liver disease. Saito and associates,⁸⁴ using RT-PCR, could find no amplification product in tissue or stool specimens from patients with biliary atresia, infantile obstructive cholangiopathy, or congenital dilation of the bile duct.

In 2009, Rauschenfels and colleagues⁷¹ did an extensive study on the incidence of hepatotropic viruses in biliary atresia. They obtained liver biopsies from 64 infants with biliary atresia at the time of the Kasai procedure. They identified reovirus type 3 RNA by RT-PCR in 21 (33%) biopsies. They noted that the 21 patients who were reovirus-positive were older (mean age 60 days) than those who were virus-negative (mean age, 54 days). This finding led them to suggest that the viral infection was a secondary phenomenon and not the cause of the biliary atresia.

Exanthem

Exanthem has been a common manifestation of clinically apparent reoviral infections.^{16,36,46,104} Lerner and associates⁴⁶ noted exanthem in six of seven children infected with reovirus type 2. Predominant symptoms in these patients included fever, malaise, anorexia, and pharyngitis. Two children had adenopathy, and one had diarrhea. The rash was maculopapular in five patients and vesicular in one child. One child had a measles-like illness with photophobia, conjunctivitis, cervical lymphadenopathy, and a confluent maculopapular rash that lasted approximately 1 week.

Exanthem has been noted in a 5-year-old girl with pneumonia and type 3 reovirus infection, a 28-month-old girl with encephalitis and type 2 infection, and an 18-year-old adolescent male with pharyngitis and cervical and posterior occipital lymph node enlargement and type 2 infection.^{16,36,104}

Neurologic Disease

Joske and colleagues³⁶ described three cases of hepatitis-encephalitis syndrome with reoviral infections. All of these cases had abnormal liver

function test results and clinical and laboratory evidence of meningeal and cerebral involvement. One child died, one had mild neurologic residua at the 6-week follow-up, and one recovered without difficulty. Two patients were infected with reovirus type 2 and one with reovirus type 3.

El-Rai and Evans¹⁶ found serologic evidence of reovirus type 2 infection in two children with aseptic meningitis, and Zalan and colleagues¹¹³ described two children with reovirus type 2 infections associated with leg weakness and pain. Johansson and colleagues³⁴ noted a 3-month-old girl with meningitis, diarrhea, vomiting, and fever. Reovirus type 1 was isolated from this child's cerebrospinal fluid (CSF), and the child had a fourfold rise in neutralizing antibody to the isolated virus. Krainer and Aronson⁴³ described a 29-year-old woman who died of disseminated demyelinating encephalomyelitis in which a reovirus was recovered from the CSF and brain. Tyler and associates¹⁰⁶ isolated a type 3 reovirus from the CSF of a 6.5-week-old child with meningitis. This child recovered without obvious neurologic sequelae.

Quattara and associates⁶⁴ reported a 6-year-old boy and his 2-month-old girl cousin with acute encephalitis associated with a reovirus type 2 infection. The boy had a febrile prodrome and then vomiting and impaired consciousness. On examination, he had a palsy of the left facial nerve. His CSF had a mildly elevated protein without pleocytosis. Magnetic resonance imaging (MRI) showed multiple symmetric lesions. He recovered completely in a few weeks. The cousin had fever, asthenia, and rhinorrhea. She also had a mildly elevated CSF protein and MRI findings similar to those of her older cousin. At hospital discharge at 18 days, she had marked hypotonia and the absence of language. At 1-year follow-up, she had uncoordinated movements. A similar virus was isolated from the urine of both children. This virus was thought to be a reassortant between human and swine strains.⁴³

Other Manifestations

A 25-year-old man with Hodgkin disease had persistent reovirus type 1 viruria for a 5-week period, but no associated clinical illness was demonstrated.¹⁵ Reoviruses have been recovered from biopsy material from patients with Burkitt lymphoma.^{2,3} One child with hemorrhagic bullous myringitis was infected with reovirus type 2.¹¹³ Terheggen and colleagues¹⁰² noted a 28-year-old man with mild myocarditis in whom a reovirus was isolated from the stool sample.

Reoviruses as Potential Anti-Cancer Agents

Studies during the present and previous decades indicate the potential of reoviruses to selectively destroy many different types of neoplastic cells.^{24,25,29,30,38,40,41,55,91,107,111,112} Many malignant cells have an activated Ras pathway that results in a deficient ability to mount an antireovirus response that is mediated by the cellular protein PKR. Organ culture and animal model systems have shown promising results with reovirus type 3 in numerous different malignant neoplasms. At present, many phase I and phase II trials are in progress or have been completed.^{25,40,41,65} Also completed is one phase III head and neck cancer trial.^{40,41}

DIAGNOSIS

Because no specific clinical features suggest reoviral infection, virologic and serologic studies are necessary for establishing the diagnosis. Reoviruses can be recovered from clinical material in primary monkey kidney tissue culture.^{76,78} Care must be taken in interpreting results, however, because reoviruses can be contaminants of monkey tissue cultures. Cytopathic effect in tissue culture is enhanced by rolling during incubation.⁴⁵ Identification of virus is made by neutralization; the distinctive cytopathic effect should be helpful in selecting strains for study with reovirus antisera. In research laboratories, reoviruses also can be detected by molecular techniques such as in situ and dot-blot hybridization and PCR.^{13,71} Paired serum specimens can be examined for antibody titer rise to reoviruses by neutralization, indirect immunofluorescent antibody technique, enzyme-linked immunosorbent assay (ELISA), or hemagglutination inhibition. Recent infection can also be identified by the demonstration of specific IgM antibody by ELISA.

With the exception of recent clinical illnesses associated with fruit bat orthoreoviruses,^{8-10,89,90,110} the vast majority of clinical associations with reoviral infections occurred more than 45 years ago. This seems surprising because recent antibody studies in sera from children indicate that infections are still common.¹⁰⁰ I believe there are several reasons for the present lack of descriptions of clinical reovirus infections. The first reason is the fact that rolling of tissue cultures in virus laboratories is rarely done today. More importantly, many diagnostic laboratories have switched from studying specimens from patients in tissue culture systems to molecular diagnostic platforms. These platforms do not include reoviruses.

In regard to clinical illness, orthoreoviruses are the forgotten viruses of the 21st century. In the 11th edition of the *ASM Manual of Clinical Microbiology*, orthoreoviruses are not mentioned at all.³²

Orbiviruses, Coltiviruses, and Seadornaviruses

Gail J. Harrison • Theodore F. Tsai

Viruses in the genera *Orbivirus*, *Coltivirus*, and *Seadornavirus* differ from others in the family Reoviridae structurally, in physicochemical properties, and by their arthropod mode of transmission.^{2,3} More than 100 orbiviruses are classified into serogroups by relationships in complement fixation, agar gel precipitation, and immunofluorescent assays. Additional serocomplex relationships are recognized, whereas individual viruses are differentiated by neutralization tests. Orbiviruses are principally animal pathogens (e.g., the bluetongue viruses); only viruses in the Kemerovo, Orungo, Lebombo, and Changuinola serogroups have been shown to cause human illness. Colorado tick fever (CTF) virus is the only *Coltivirus* recognized to cause human illness, and among the seadornaviruses, only Banna virus (BAV) is a confirmed human pathogen.^{2-4,50,54}

The orbiviruses are spherical nonenveloped viruses with two protein shells: an outer shell (capsid) approximately 86 nm in diameter and an inner shell (core) 69 nm in diameter. The inner core VP7 protein, arranged in trimers, contains group-reactive antigens, and the outer capsid VP2 or VP5 proteins bear serotype-specific antigens. The viruses are acid labile, and some exhibit sensitivity to lipid solvents. The double-stranded RNA viral genome comprises 10 segments associated with viral structural and nonstructural proteins. Their complete nucleotide sequences and coding assignments have been determined for a bluetongue virus, and partial information is available for others. In general, reassortments of genomic segments among viruses within serogroups are viable, but not between groups, thus validating the broad serogroup classification. The genetic relationships (e.g., RNA hybridization) among viruses within serogroups diverge from the antigenic relationships in some instances, providing an additional basis for taxonomic classification.

The coltiviruses and seadornaviruses resemble the orbiviruses in size and in having two capsids but possess genomes organized into 12 RNA segments.³ The morphologic features and structural protein similarities of seadornaviruses and rotaviruses suggest an evolutionary relationship.⁴⁰

COLORADO TICK FEVER VIRUS

CTF virus is an acute tick-borne febrile illness caused by the eponymous *Coltivirus*.^{5,13,18,19,30,48,51} Eyach virus, isolated from *Ixodes* ticks in France and Germany; S6-1403, isolated in California from a gray squirrel; and mosquito strains from Indonesia are related to but distinct from CTF virus and have not been confirmed to cause human illness.^{3,29-31} RNA hybridization studies of CTF viral strains from a 33-year interval found

minor heterogeneity, thus suggesting that a single gene pool has been maintained by mixing of viral strains and by constraints on viral replication within tick vectors and vertebrate hosts. Molecular characterization of the virus also continues by basic scientists.⁴³ A wide variety of small and large mammals are infected naturally with the virus, but clinical illness develops only in humans. Experimental infection of rhesus monkeys, hamsters, and mice produces hematologic changes similar to those occurring in human infections.²²

Epidemiology

Cases occur sporadically in association with the habitats of the wood tick *Dermacentor andersoni*.⁵⁵ Most cases occur in May and June, when adult ticks are most active, but infections from March to November have been reported. Infections are acquired principally in the western part of the United States, especially Wyoming and Utah; Canada in the known geographic distribution of the vector; and at elevations between 4000 and 10,000 feet (Figs. 172.1 and 172.2).^{8,11,12,13,46,47,55} In one study in Wyoming, 99% of the ticks reported were *D. andersoni*, found in areas with sagebrush at elevations higher than 7000 feet.²¹ In rare cases, CTF has occurred in persons who had not traveled to areas of known risk, such as those exposed to ticks brought home on the clothing of family members and, in one case, by transfusion.^{7,39,45,46,54} The annual incidence of disease in the Rocky Mountain region, approximately three per 1 million residents, is declining, possibly a result of a larger elk population that has reduced habitats of small vertebrate hosts.⁴

CTF virus is maintained in a 2- to 3-year cycle among small mammals, principally rodents, and *D. andersoni* ticks (Fig. 172.3).^{5,13,19} Once infected in the larval stage, ticks remain infected through the nymphal and adult stages (transstadial transmission). Larvae are infected by viremic rodents. After molting, they carry the virus through the winter, and as nymphs, they infect other rodents and renew the cycle of transmission the following spring. Humans become infected incidentally by the bite of infected adult ticks (Fig. 172.4).

The least chipmunk (*Eutamias minimus*), the golden-mantled ground squirrel (*Spermophilus lateralis*), and the porcupine (*Erethizon dorsatum*) appear to be the primary hosts for larval, nymphal, and adult *D. andersoni*; secondary hosts include rock mice (*Peromyscus maniculatus*), meadow voles (*Microtus pennsylvanicus*), and pine squirrels (*Tamiasciurus hudsonicus*).⁶

D. andersoni is found exclusively in the high plains and in mountainous terrain between 4000 and 10,000 feet in altitude in the geographic distribution previously mentioned. The specific microhabitats where

FIG. 172.1 Geographic distribution of *Dermacentor andersoni* ticks and reported cases of Colorado tick fever, 1980–91.

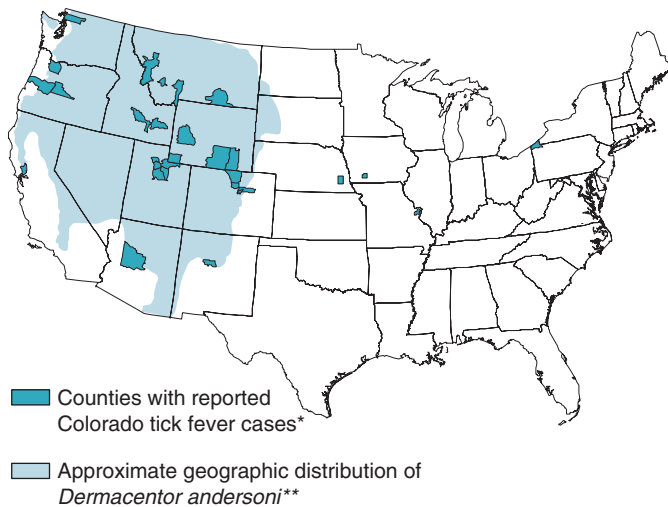

FIG. 172.2 Approximate geographic distribution of *Dermacentor andersoni* ticks and counties of residence for confirmed and probable Colorado tick fever virus disease cases, United States, 2002–12. (Courtesy Centers for Disease Control and Prevention. Available at: <https://www.cdc.gov/coloradotickfever/statistics.html>.)

infected ticks are most prevalent are south-facing slopes with open stands of ponderosa pine, moderate shrubs, and rocky surfaces that provide favorable habitats for the intermediate rodent hosts.^{6,38} Both male and female adult ticks can transmit infection to humans, and the period of attachment required for transmission of the virus may be very brief.

Clinical Manifestations

A history of a tick bite or tick exposure is given by more than 90% of patients.²³ The incubation period usually is 3 to 4 days, with a range

FIG. 172.3 Adult male (left) and female (right) *Dermacentor andersoni* ticks. Both can transmit Colorado tick fever virus.

Ecology of Colorado Tick Fever Virus

Colorado tick fever (CTF) virus is spread by Rocky Mountain wood ticks (*Dermacentor andersoni*). Rocky mountain wood ticks are found in the western United States and Canada at 4,000–10,000 feet above sea level. Here are the steps in how the virus is spread:

FIG. 172.4 Colorado tick fever virus ecology. (Courtesy Centers for Disease Control and Prevention. Available at <https://www.cdc.gov/coloradotickfever/transmission.html>.)

of 0 to 14 days after known exposure to a tick.^{4,23} The onset typically is abrupt, with fever, chills, malaise, headache, retroorbital pain, myalgia, lumbar pain, and hyperesthesia. Nausea, vomiting, and abdominal pain occur less frequently. Upper respiratory tract symptoms usually are absent, although conjunctival injection may develop. Lymphadenopathy and hepatosplenomegaly are found in some patients. Maculopapular and petechial eruptions have been observed in 5% to 12% of cases.⁴⁹

The disease classically is biphasic; an initial attack lasting 2 to 3 days is followed by an equal interval of defervescence and a second and, rarely, a third recurrence. However, this saddleback pattern is absent in more than 50% of cases. Symptoms resolve several days after the second bout of fever, but prolonged asthenia lasting for several weeks is a typical finding, especially in adults.²³

Leukopenia is a hallmark of the illness. The mean initial leukocyte count is 3900/mm³, which diminishes to a nadir 5 to 6 days after the onset of illness, often during the period of remission. A left shift with an absolute neutropenia and relative lymphocytosis is a usual finding. Examination of bone marrow aspirates shows maturational arrest in the granulocytic series, with absent mature forms and numerous metamyelocytes and myelocytes. Megakaryocytes are depleted, and a reduced peripheral platelet count (<150,000/mm³) is found in most patients; however, thrombocytopenia rarely reaches a level of clinical significance to cause bleeding.^{28,36}

Uncomplicated recovery is the rule. Epididymo-orchitis, pneumonitis, hepatitis, and pericarditis have been reported as complications, but the most serious complications are encephalitis and hemorrhage,^{16,20,23,25,37} which have been reported nearly exclusively in children younger than 10 years.^{11,23,50} Three deaths have been reported, all in children who exhibited signs of generalized bleeding accompanied by a reduced platelet count.^{23,28} Examination of the bone marrow in one child disclosed a generalized depression of myeloid and erythroid elements and a marked reduction in megakaryocytes. Central nervous system signs consistent with meningitis and encephalitis, sometimes associated with coma, have been reported in both children and adults. Examination of cerebrospinal fluid disclosed elevated protein and mononuclear cell pleocytosis in the few cases that have been described.

D. andersoni is a vector for both CTF and Rocky Mountain spotted fever.³ Although dual isolation of CTF virus and *Rickettsia rickettsii* from the same tick has not been reported, a concurrent rickettsial infection could not be discounted in all of the previously mentioned fatal cases attributed to CTF. Furthermore, a dual infection could develop in an individual exposed to more than one tick.

CTF virus is teratogenic in experimentally infected mice, but few clinical data are available on the teratogenic potential of the virus in humans.^{24,27} One pregnant woman aborted 2 weeks after having an illness; and in an infant delivered 6 days after the onset of CTF in the mother, a febrile illness with leukopenia developed at 3 days of age, thus indicating a possible vertically acquired infection. In a single reported instance, a second attack of CTF has been documented, which indicates that immunity may not be permanent.^{23,24}

The combined historical elements of tick exposure and outdoor activity in an enzootic area should suggest the diagnosis in patients with a spring-summer grippelike illness. In a controlled study, abdominal pain, pharyngitis, and rash were less common symptoms in patients with CTF than in patients with other acute illnesses in the same season. Although Rocky Mountain spotted fever occurs rarely in the states in which CTF is prevalent, the possibility of this potentially fatal disease should be considered in the differential diagnosis. Helpful differentiating features include the rarity of a petechial rash in CTF and its biphasic course. Tick-borne relapsing fever also follows a remitting course, but it has a more acute and toxic onset; splenomegaly occurs commonly, and remission is by crisis. The geographic distribution of the diseases overlaps; however, human encounters with the argasid (soft) tick vectors of relapsing fever (*Ornithodoros* ticks) are likely to occur in cabins and other protected areas.

Eyach virus has been implicated in central nervous system infections and polyradiculitis in Europe. However, its tick-borne transmission from *Ixodes ricinus* that also transmits *Borrelia*, *Anaplasma*, and Kemerovo group viruses has prevented establishment of a clear interpretation.

Pathophysiology

Experimental infection of rhesus monkeys, rodents, and human marrow cells in vitro has shown that CTF virus infects the erythropoietic elements (erythroblasts to reticulocytes) at an early stage of infection.^{13,14,22,28,45,47} After the infected cells mature and are released into the peripheral circulation, the virus persists intracellularly, where it has been identified by electron microscopy.^{15,44,45} CTF virus has been cultured from circulating

erythrocytes for up to 120 days after the onset of illness.²⁷ Red cell survival evidently is not shortened, and infected cells circulate in the presence of neutralizing antibody. Prolonged viremia has not been associated with either a protracted or a more severe course of illness. Infected CD34+ progenitor cells and impaired mononuclear cell production of colony-stimulating factors may contribute to the acute regenerative cytopenia.^{44,45} High levels of serum interferon- γ correlate with fever during the acute phase of illness.¹

Laboratory Diagnosis

The most readily available diagnostic test is reverse transcriptase-polymerase chain reaction (RT-PCR) detection of viral RNA or virus-specific immunoglobulin M (IgM) in serum.^{31,44} Cerebrospinal fluid may also be tested. Testing is available in some commercial and state health laboratories and at the Centers for Disease Control and Prevention Division of Vector-Borne Diseases Arbovirus Diagnostic Laboratory (<https://www.cdc.gov/ncezid/dvbd/specimensub/arboviral-shipping.html>).

RT-PCR may be positive on the first day of illness, and IgG seroconversion usually occurs within 14 to 21 days. Direct immunofluorescent examination of blood smears for intraerythrocytic viral antigen is also a rapid approach to laboratory diagnosis.^{14,31} Isolation of virus from acute or convalescent blood samples in baby mice or Vero or BHK cells also can be done.^{10,14} Freezing and thawing of the clot should be avoided, and it should instead be refrigerated for short-term storage. Virus has been isolated from a blood clot that had been refrigerated for 14 months. Serologic diagnosis by demonstration of fourfold rises in neutralizing, complement fixation, immunofluorescent, or enzyme-linked immunosorbent assay (ELISA) antibody is confirmatory. ELISAs that distinguish between CTF and Eyach virus antibodies are available. Neutralizing antibody rises slowly; only one-third of patients had detectable neutralizing antibody 10 days after onset, but fourfold rises appeared within 30 days of onset in 92%. Therefore acute serum should be collected 3 to 10 days after onset of symptoms, and convalescent serum for IgG antibody testing should be done at least 14 to 21 days after the acute serum.

Treatment

No specific therapy is available. Because thrombocytopenia may occur and hemorrhage is a reported complication in children, antipyretics that interfere with coagulation should not be used.

Prevention

Repellents containing permethrin should be sprayed on clothing, and repellents containing diethyltoluamide (DEET) or picaridin should be applied to exposed skin. Long pants should be tucked into socks and shirts tucked into slacks. Clothing, gear, and skin should be inspected frequently for unattached and attached ticks, especially if walking through sagebrush or spending time at elevations higher than 7000 feet.^{21,22} Light-colored clothing facilitates such inspections. One case of human-to-human transmission by transfusion of infected blood has been reported.⁷ Persons with documented CTF should be prohibited from donating blood until the often prolonged viremia has cleared.^{46,47}

BANNA VIRUS

BAV is the prototype species of *Seadornavirus* within the family Reoviridae. It is a segmented double-stranded RNA virus with 12 segments in its genome.^{34,35} It was originally isolated in patients with encephalitis in Xishuangbanna, Yunnan Province, People's Republic of China, from which it received its name. It is also found in mosquitoes in China, Vietnam, and Indonesia, and likely is distributed from the tropics of Southeast Asia to the northern temperate regions of China (Fig. 172.5).

BAV has been isolated from patients with febrile illness and encephalitis in China and is believed to be a major contributor to cases of viral encephalitis in China and, possibly, within a broader region of East and Southeast Asia.^{2,32,35,50} It has been isolated from 10 different mosquito species from two genera (*Culex tritaeniorhynchus*, *Culex pipiens pallens*, *Culex annulus*, *Culex pseudovishnui*, *Culex modestus*, *Anopheles sinensis*, *Aedes vagus*, *Aedes albopictus*, *Aedes vexans*, and *Aedes dorsalis*), which

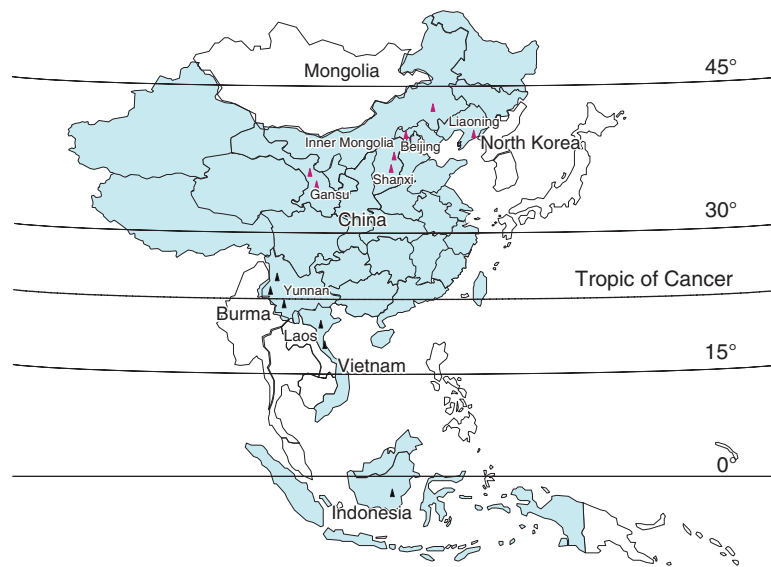

FIG. 172.5 Location of Banna viruses in China and southeast Asia countries of Vietnam and Indonesia (shaded areas). Distinct areas of virus isolation from mosquitoes are shown (triangles). (Courtesy Centers for Disease Control and Prevention. Available at: <https://wwwnc.cdc.gov/eid/article/16/3/09-1160-f1>.)

are widely distributed in China and other areas of the world.²⁶ A common ancestry and taxonomic link to rotaviruses have been indicated by similarities in the viruses' gene organization and certain gene segment sequences (e.g., for VP9), as well as their morphology.⁴¹ Two genotypes/serotypes (A and B) have been defined with broadly overlapping geographic distributions. The virus has been isolated from far-northern China, Mongolia, southern China, Vietnam, and Indonesia and from *C. tritaeniorhynchus*, *C. pipiens pallens*, and other mosquito vectors that also transmit Japanese encephalitis virus (JEV), and, in one study, the virus was implicated as the cause of 14% of cases in a nominal JEV outbreak.^{33,35,42} In addition, although the transmission dynamics of BAV are not well known, it is possible the virus may spread by infected mosquitoes caught by prevailing winds that move from South East Asia to East Asia, or associated with bird migration through East Asia–Australasia flyways.

Clinical symptoms in confirmed cases have included fever, arthralgia, and encephalitis, but few details have been published.

BAV appears to be an emerging virus with possible spread into nonendemic areas.

The potential public health impact of BAV infection could be substantial in the near future.^{34,35} The diagnostic tests to confirm a specific diagnosis are not widely available; broader application of real-time PCR assays that have been developed and field studies are needed to define the burden of disease and need for public health intervention. In addition, several seadornaviruses related to BAV that have been described in China (e.g., mosquito-borne Liao ning virus, Balaton virus, and Mangshi virus) are suspected to cause human illness but currently remain orphan agents.^{37,54}

KEMEROVO AND RELATED VIRUSES

The Kemerovo serogroup comprises tick-borne Kemerovo, Tribec, and Lipovnik viruses, which may have descended from ancestral mosquito-borne orbiviruses.⁹ Kemerovo virus, a double-stranded RNA virus, was isolated from the cerebrospinal fluid of two patients with encephalitis and from ticks in the Kemerovo region of Russia; seroconversion was demonstrated in 10 other patients with meningoencephalitis with tick bites and in whom Russian spring-summer encephalitis was excluded.^{8,33} The virus is transmitted in an *Ixodes persulcatus*–rodent cycle. Lipovnik virus has been reported in neurologic infections in the former Czechoslovakia, where flaviviral tick-borne encephalitis is endemic; one study showed seroconversion to Lipovnik virus in half of the patients with encephalitis who were studied, including some with suspected dual infection with tick-borne encephalitis virus.³² This finding seems plausible because both viruses are transmitted by *I. ricinus* ticks, and multiple

exposure to singly infected ticks or infection with a dually infected tick may be possible. In addition, serologic evidence of Lipovnik or Tribec infection was reported in patients with chronic polyradiculoneuritis; however, spirochetal infection was not ruled out in these cases. The increasing geographic range of *I. ricinus* ticks in Europe to more northerly latitudes and higher elevations, attributed to global warming, could lead to increased transmission of these orbiviruses, as has been observed with tick-borne encephalitis virus.

On the basis of serologic rises in patients with acute febrile illness diagnosed clinically as Rocky Mountain spotted fever, a Kemerovo-related virus is suspected to occur in the southwestern region of the United States. Patients with a history of a tick bite or tick exposure, whose sera were negative for *R. rickettsii*, demonstrated fourfold or greater changes in immunofluorescent titers to Lipovnik and Six Gun City viruses (Kemerovo group).^{52,53} Rises in immunofluorescent antibody titers to 128 to 512 suggested recent infection with a Kemerovo-related virus, possibly a novel agent or related to rabbit syncytium virus, which is enzootic in the United States. The patients had acute febrile illnesses with myalgia, vomiting, and severe abdominal pain, along with leukopenia, thrombocytopenia, and anemia, similar to Rocky Mountain spotted fever. No agent was isolated from the patients, but neither was the possibility of *Ehrlichia* infection excluded. Quantitative PCR assays are also being developed to detect Kemerovo virus in mosquitoes and clinical specimens from humans.^{52,53}

ORUNGO VIRUS

Orungo virus is unrelated antigenically to the other orbiviruses. Infection is prevalent in western, central, and eastern Africa and apparently is transmitted in a sylvatic monkey, with an *Aedes* mosquito cycle similar to that of yellow fever. Human-to-human transmission by *Anopheles* mosquitoes is speculated to occur. The virus is primarily a zoonotic infection of livestock and wildlife. However, it has been isolated from patients with fever and headache, and serologic evidence of infection has been reported in outbreaks of illness characterized by fever, headache, myalgia, nausea, and vomiting. Seroconversion has been observed in patients studied during yellow fever outbreaks, presumably because of concurrent transmission of the viruses. The virus also was isolated from the blood of a child with seizures and flaccid paralysis.^{17,42}

LEBOMBO VIRUS

Lebombo virus is not grouped antigenically. The virus was isolated first from *Aedes circumluteolus* mosquitoes in South Africa. Subsequently,

the virus was recovered from a Nigerian child with nonspecific febrile illness; the virus also was isolated from rodents and mosquitoes in Nigeria.⁴²

CHANGUINOLA VIRUS

Changuinola virus belongs to an antigenic complex of 12 principally phlebotomine-borne orbiviruses. The virus is transmitted in Panama among forest mammals and *Phlebotomus* flies. Only one human case has been reported—a nonspecific febrile illness in a mosquito catcher.

Rotavirus

Timo Vesikari • Maria Hemming-Harlo • Suvi Heinimäki

Before universal rotavirus vaccinations, rotaviruses were the single most important cause of severe gastroenteritis of young children worldwide.^{187,234} In the United States, rotaviruses were estimated to cause 55,000 to 70,000 hospitalizations (one in 72 children before the age of 5 years) and 20 to 60 deaths in young children annually before rotavirus vaccination.^{83,84,188} In Europe, the number of hospitalizations was estimated at 87,000 (one in 54) per year.²²⁸ Globally rotaviruses were estimated to be responsible each year for 453,000 deaths in children younger than 5 years at the time rotavirus vaccination was being introduced.²³⁴ A more recent, and realistic, estimate puts the number at 197,000.¹³⁴ The latter is in line with the recent estimate of 0.6 million for total childhood mortality from acute diarrhea.¹⁴³ Deaths from acute diarrhea have greatly decreased in the past two decades because of better case management and improved sanitation and hygiene.

Rotavirus disease consists of diarrhea and vomiting accompanied by fever, a combination that may produce severe dehydration in infants and young children. Most deaths are due to dehydration and can be prevented by active rehydration therapy. Rotavirus infection is also associated with viremia (more often antigenemia) and may also cause extraintestinal symptoms.

Even though effective case management and “nonspecific” prevention have decreased rotavirus mortality over the past 25 years, rotavirus remains an important target for vaccination. Successful use of rotavirus vaccine has shown that rotavirus gastroenteritis (RVGE) is a vaccine-preventable disease. Since the introduction of rotavirus vaccines in 2006, RVGE has been drastically reduced in countries that have implemented universal vaccination, including the United States, Latin America, and many European countries. From Latin America, there is evidence that universal rotavirus vaccination has significantly reduced deaths from all-cause diarrhea.^{193,213}

Human rotaviruses were discovered in 1973 by Bishop and colleagues based on electron microscopy (EM) of duodenal mucosa specimens from children with acute gastroenteritis.²¹ At almost the same time, Flewett and coworkers demonstrated rotaviruses in stools by EM,⁶⁶ and EM of stools became the preferred diagnostic method for several years. Cultivation of human rotaviruses became possible when it was discovered that the viruses should be treated with trypsin to cleave the surface

protein VP4.^{37,54} This paved way for the development of human rotavirus vaccines.²³⁶ Even earlier, animal (bovine and rhesus monkey) rotaviruses had been propagated in tissue culture to produce live (naturally) attenuated rotavirus vaccines that cross-protected against human rotavirus disease by sharing the common group A VP6 antigen, which is a major immunogenic protein of the rotavirus particle.²³²

ROTAVIRUSES

Rotaviruses are nonenveloped viruses with a segmented double-stranded RNA (dsRNA) genome. The name *Rotavirus* (Latin *rota*, meaning “wheel”) originates from the distinctive wheel-like appearance of the complete virus particles visualized under electron microscope.⁶⁵ The mature infectious rotavirus particles consist of three concentric protein layers, therefore also called triple-layered particles (TLPs; Fig. 173.1A).

The innermost layer of the virion comprises 60 dimers of a VP2 protein (see Fig. 173.1B) enclosing the genome.²²⁴ Complexes of two minor structural proteins, one copy of the viral RNA-dependent RNA polymerase VP1 and the viral capping enzyme VP3, are anchored to the inner surface of VP2 core shell (see Fig. 173.1B).^{137,202} A middle layer consisting of 260 trimers of the VP6 protein surrounds the core (see Fig. 173.1B), forming a noninfectious but transcriptionally active double-layered particle (DLP).^{160,167} The inner capsid protein VP6 is highly immunogenic and is the most abundant rotavirus protein.^{110,232} VP6 is in direct contact with the core and external layers of the virus (see Fig. 173.1C). The outer layer is formed by 260 trimers of the VP7 glycoprotein, each trimer anchored to the underlying VP6 layer, and 60 spikes of VP4 trimers projecting from the VP7 shell (see Figs. 173.1B–C).^{203,224} The VP7 and VP4 proteins serve as viral attachment proteins and neutralization antigens.^{147,221} Proteolytic cleavage of VP4 protein into VP8* and VP5* fragments (see Fig. 173.1C) leads to the fully infectious TLP.^{37,54}

A distinctive characteristic of the structure of rotavirus virion is the presence of 132 large channels of three types, which penetrate through the VP6 and VP7 layers.²⁰³ These channels include 12 type I channels located at the fivefold axes, 60 type II channels surrounding the type I channels, and 60 type III channels around the threefold axes.

FIG. 173.1 Structure of rotavirus triple-layered particle (TLP) consisting of a VP2 core, a VP6 inner capsid and an outer capsid of VP7 with VP4 (VP5* + VP8*) spikes. (A) Electron microscopy image of TLPs. (B) Cutaway view of TLP demonstrating the VP7 layer with VP4 spikes, VP6 layer, VP2 core, and the transcriptional enzyme complex of VP1 and VP3 anchored to the inner surface of VP2. (C) Interactions of structural proteins. (B, Modified from Jayaram H, Estes MK, Prasad BV. Emerging themes in rotavirus cell entry, genome organization, transcription and replication. *Virus Res.* 2004;101:67-81. C, From Settembre EC, Chen JZ, Dormitzer PR, Grigorieff N, Harrison SC. Atomic model of an infectious rotavirus particle. *EMBO J.* 2011;30:408-416.)

The rotavirus genome consists of 11 dsRNA segments encoding six structural viral proteins (VP1–VP4, VP6, and VP7) and six non-structural proteins (NSP1–NSP6). Each segment encodes one protein with the exception of segment 11, which codes for two proteins (NSP5/NSP6) because of overlapping open reading frames.¹⁶⁶ The nonstructural proteins are involved in replication, virus particle assembly, regulation of the host immune responses, and stimulation of viral gene expression.^{12,15,55,235}

Classification and Strain Diversity

Rotaviruses can be classified into five groups (A–E) and three tentative groups (F–H) according to their antigenic properties or, more recently, the amino acid sequences of the VP6 protein. Group A rotaviruses cause more than 90% of human infections. Rotaviruses of groups B and C have been occasionally associated with diarrheal disease, primarily in older children and adults.

Within group A, rotaviruses are further divided into four subgroups (SGs) referred to as SGI, II, I-II, and non-I/II, based on the presence or absence of two SG-specific epitopes on VP6.⁹¹ Human strains belong predominantly to either SGI or SGII.^{113,201,238} Rotaviruses of group A have also been designated G- and P-serotypes according to the reactivity of VP7 (G for glycoprotein) and VP4 (P for protease-sensitive) antigens with reference antisera in neutralization assays.¹⁰⁵ At present, the rotavirus strains are classified into G- and P-genotypes based on the sequences of the VP7 and VP4 gene segments.^{77,88} G-serotypes correspond one-to-one with G-genotypes, whereas part of P-serotypes comprise several P-genotypes. To date, 27 G-genotypes (G1–G27) and 37 P-genotypes (P[1]–P[37]) have been identified for rotaviruses.^{164,241} In contrast, 14 P-serotypes, of which serotypes 1, 2, and 5 are further divided into subtypes with letter designations, have currently been discriminated. This has led to a double nomenclature for P-types in which the P-genotype is enclosed in square brackets after the P-serotype designation together with a possible subtype letter (e.g., P1A[8]). In practice, P-types are commonly denoted by their genotypes only.

The gene segments of rotaviruses can occasionally reassort during coinfections with different genotypes, leading to reassortant strains with segments originating from the two parent strains. More than 70 distinct G-P genotype combinations of human rotavirus strains belonging to the 12 G-types and 15 P-types have been identified, but only 5 G-types (G1, G2, G3, G4, and G9) and 3 P-types (P[4], P[6] and P[8]) are frequently associated with human diseases.⁷⁹ Still, the majority of rotavirus infections are associated with only five globally circulating genotype

combinations: G1P[8], G2P[4], G3P[8], G4P[8], and G9P[8], of which G1P[8] strains are most common.⁴⁹ In developing countries, the incidence of strains with unusual genotypes (e.g., G8 and G12) as well as unusual genotype combinations (e.g., G1P[4], G2P[8] and G4P[6]) is higher.^{13,223}

A novel comprehensive nucleotide-sequence-based classification system taking into account the complete genome of the virus was recently introduced as an extension to the binary G- and P-typing classification.^{163,164} In the full genome classification system, the abbreviations Gx-P[x]-Ix-Rx-Cx-Mx-Ax-Nx-Tx-Ex-Hx represent genotypes of the gene segments respectively encoding VP7-VP4-VP6-VP1-VP2-VP3-NSP1-NSP2-NSP3-NSP4-NSP5/6. Currently, at least 27 G, 37 P, 17 I, 9 R, 9 C, 8 M, 18 A, 10 N, 12 T, 15 E, and 11 H genotypes have been differentiated according to cutoff points of nucleotide sequence identities. Regardless of the wide diversity rotaviruses exhibit, the majority of human rotaviruses appear to belong to two major genotype constellations sharing most of the genotypes of the internal non-G and non-P genes. Genotypes 1 (I1-R1-C1-M1-A1-N1-T1-E1-H1) are commonly encountered in combination with P[8] and various G-genotypes, and genotypes 2 (I2-R2-C2-M2-A2-N2-T2-E2-H2) with G2P[4].¹⁶⁵

ROTAVIRUS INFECTION

Reproductive Cycle of Rotavirus

Rotaviruses infect nondividing mature enterocytes at the tips of the villi of the small intestine. Rotavirus infection depends on activation of the TLPs, involving cleavage of the VP4 into VP8* and VP5* (see Fig. 173.1C) by trypsin-like proteases in the intestinal lumen. VP8* domains located at the activated spike tips of the infectious TLPs can bind to sialic acids in the cellular glycans.^{52,62} Recently, histo-blood group antigens (HBGAs) present on the surface of mucosal epithelial cells have also been described as receptors for certain rotavirus strains via binding of VP8*.^{106,107} Other cell proteins implicated in rotavirus entry as probable coreceptors in a postattachment step include various cellular integrins and heat shock cognate protein 70 (hsc70) interacting with VP5* or VP7.^{42,90,96,278} Following binding, the virus is internalized by receptor-mediated endocytosis, or direct membrane penetration and removal of the outer-layer proteins during entry leads to the release of transcriptionally active DLPs into the cytoplasm.^{144,148,224,273,275}

Transcription complexes consisting of VP1 and VP3, localized at the inferior side of the VP2 core,²⁰² initiate the transcription of the 11 dsRNA gene segments. The synthesized capped plus-strand RNAs are extruded via type I channels passing through the layers of VP2 and

VP6, each channel possibly extruding transcripts of a specific gene segment.¹⁹⁸ The transcription products serve as mRNAs for viral protein synthesis and as templates for synthesis of the minus-strand RNAs and formation of dsRNAs.^{118,194}

Once a critical amount of viral proteins is synthesized, structural VP1, VP2, VP3, and VP6 and nonstructural NSP2, NSP5 and NSP6 proteins accumulate in large cytoplasmic inclusion bodies, “viroplasms,” where replication, packing of genome, and assembly of DLPs occur. The presence of NSP2 and NSP5 has been found to be essential for the formation of viroplasms.⁵⁵ Viroplasm-associated plus-strand RNAs interacting with core proteins are packed into assembling VP2 cores and thereafter replicated into the dsRNAs by VP1 polymerase.²²⁶ Core particles are coated with VP6 trimers, resulting in the formation of DLPs that bud into the endoplasmic reticulum via NSP4 transmembrane protein.^{235,236} Subsequent assembly of VP4 and VP7 proteins completes the formation of TLPs, and release of the mature progeny virions from the infected cell occurs via direct cell lysis or a nonclassical vesicular transport mechanism.^{121,172}

Transmission

Rotaviruses are highly infectious and transmitted via the fecal-oral route, in respiratory droplets or via fecally contaminated water.^{4,68} Infected children start shedding rotaviruses in their stools before the onset of symptoms²⁰⁰ and may excrete more than 10^{10} or 10^{11} rotavirus particles per gram of feces; fewer than 100 particles are required to infect new contacts.^{64,124,265} The peak viral shedding in stools occurs on the third day of illness, and half of rotavirus-infected children shed for 10 days.²⁶¹ Prolonged shedding has been reported in immunocompromised children.²¹²

ROTAVIRUS DISEASE

Pathogenesis

The clinical symptoms of primary rotavirus infection commonly start after a 48-hour incubation period, with forceful vomiting followed by fever and diarrhea. The symptoms usually last from 4 to 7 days.²⁴² Rotavirus infection may potentially cause elevation of transaminase levels and, in complicated diseases, seizures and encephalitis.^{38,128,185,237} In several studies, the rotavirus viremia and/or antigenemia has been found to contribute to the clinical manifestations of rotavirus infections, as children detected with rotavirus RNA in serum are likely to have more severe vomiting and higher fever than those with rotavirus only in stools.^{46,60,100} However, the antigen level has also been found to be associated with the probability of convulsions and level of interleukin 8 and 10 in rotavirus-infected children.^{32,60,74,231}

Diarrhea

The most typical sign of rotavirus infection, diarrhea, may be caused by several mechanisms; it may be osmotic, secretory, and/or exudative.^{59,151} Rotavirus diarrhea has been explained by damage to the epithelial cell line and by changes in the intracellular Ca^{2+} concentrations. After infection of mature enterocytes at the tip of the villi, the intracellular Ca^{2+} concentration increases, leading to inhibition of Na^+ cotransporters, which reduces the absorptive capacity of the intestinal epithelium. The unabsorbed organic molecules increase the osmolality of the intestinal contents and absorb water from the epithelium, causing osmotic diarrhea. The increase of intracellular Ca^{2+} concentration is caused by NSP4, which also may stimulate the release of serotonin 5-hydroxytryptamine (5-HT) from the enterochromaffin cells, activating the enteric nervous system. In addition, NSP4 results in disruption of tight junctions of enterocytes while stimulating secretion in crypt cells.^{97,108,109,150,176}

Vomiting

Rotavirus infection causes delay in gastric emptying, which changes the pressure between stomach and duodenum.¹⁴ The pathology of gastric delay includes stimulation of vagal nerves and gastrointestinal hormones, mediated by the 5-HT₃ receptors and sodium glucose co-transporter (SGLT-1).^{174,208} During rotavirus infection intestinal enterochromaffin cells release 5-HT, which interacts with 5-HT₃ receptors and stimulates the vagal afferent nerve projecting to the vomiting center of the brain.⁹⁷

Fever

Rotavirus-infected children often have fever, as the infection stimulates the release of several pyrogens, such as prostaglandins and interleukin, from infected cells. In addition to their temperature-modulating effect, prostaglandins (PGE_2) may stimulate water secretion.²⁷⁴

Extraintestinal Spread

Rotaviruses may spread from the intestines into the circulation, as rotavirus RNA and rotavirus antigen have been detected in serum of infected children. The presence of rotavirus RNA or antigens in sera is not genotype specific.^{23,24,116} In several studies, antigenemia has been found to correlate with rotavirus load in stools.⁴⁶

Rotavirus RNAemia and antigenemia are common events, occurring in 58% to 72% and 33% to 90%, respectively, of rotavirus-infected children. Extraintestinal spread of rotavirus into cerebrospinal fluid has been described in case reports, and rotavirus RNA has been detected in multiple extraintestinal organs, such as heart, kidney, spleen, testes, bladder, and liver.^{140,152,177,179,237} Even though the presence of rotavirus RNA and antigen in serum implies the presence of infectious rotavirus particles in blood, the isolation and culture of such infectious particles from human serum has been largely unsuccessful, apart from one study in which the infectious rotavirus particles were detected in HT-29 cells.²⁴ In the same study, the detection of antigenemia was found to be directly related to the presence of viral particles in serum. However, the presence of rotavirus RNA might be fully explainable by excess production of free viral proteins or release of noninfectious rotavirus particles (DLPs) from the intestines into the serum without any extraintestinal replication. It is plausible that previous rotavirus infections may reduce the extraintestinal spread of the virus and restrict the infection to the intestines, as an inverse association between baseline serum IgG titers and levels of serum antigen and serum RNA has been found.²⁰⁷

EPIDEMIOLOGY

Seasonality

In regions with a temperate climate, such as Europe or the United States, rotavirus has a clear seasonal distribution, the most active months being in the winter and/or early spring.^{84,131} In subtropical and tropical climates, the distribution of rotavirus disease is not as clear as in Europe; the most active months are during the cool and dry season, but sporadic infections may be detected during the whole year.⁹⁹

Genotype Distribution

Around the world, the most common circulating genotype before rotavirus vaccination was G1P[8] followed by G4P[8].^{29,78} The most common genotypes—G1P[8], G2P[4], G3P[8], G4P[8], and G9P[8]—accounted for 86% to 99% of rotavirus infections in European countries.⁴⁹

Fluctuations in the predominant genotypes are relatively frequent (such as shifts from G1P[8] to G4P[8]), but the shift commonly occurs within those genotypes. G1P[8] accounted for 78.5% of all rotavirus infections in the United States between 1996 and 2005, followed by G2P[4], G9P[8], and G3P[8] (9.2%, 3.6%, and 1.7%, respectively).⁷⁸ Similarly in Europe, for example in Finland, the most common rotavirus genotypes were G1P[8] (62%) and G9P[8] (12%), and other common genotypes, G4P[8], G2P[4], and G3P[8], were observed to a lesser extent.²⁰⁵

In Latin America, the same common genotypes account for the majority of the infections, but the annual genotype distribution is broader (Fig. 173.2). In developing area countries of Africa and Asia, more uncommon genotypes (such as G12 and G8) and different G- and P-type constellations (such as G12P[6] or G2P[8]) were and still are detected often.^{29,43,129,175}

The implementation of rotavirus vaccination has changed the natural seasonality and genotype distribution of rotavirus disease. In the United States, a biennial pattern of rotavirus activity and delay in the most active months has been observed after mass vaccinations.¹⁹⁵ Altogether more variety in genotypes has been seen in countries that have implemented universal rotavirus vaccination, such as the United States and Finland (see later discussion).

FIG. 173.2 Rotavirus genotypes in Finland, the United States, and Latin America before universal mass vaccination.

Age

Before the introduction of rotavirus vaccines, rotaviruses were the single most important cause of severe gastroenteritis of young children worldwide. Each child is infected at least once before the age of 5, the majority before their second birthday.⁸⁴ The occurrence of primary rotavirus infection is earlier in developing countries, possibly due to year-round exposure to rotavirus and high environmental viral loads. Generally, rotavirus causes the most severe gastroenteritis in infants and young children between the ages of 6 and 24 months.^{157,242} Neonatal and adult rotavirus infections are less common and often asymptomatic; however, rotavirus may cause outbreaks in places such as retirement homes and neonatal units.^{3,20,132} In a recent Finnish study of rotavirus epidemiology in adults, severe gastroenteritis due to rotavirus infection was detected mainly in the elderly (median age, 80 years); however, the burden of disease in elderly is small compared to that in young children.¹⁵⁹

LABORATORY DIAGNOSIS

The first diagnostic method was demonstration of rotavirus particles by electron microscopy (EM) in stools.⁶⁶ An enzyme-linked immunosorbent assay (ELISA) detection method was developed soon after discovery,²⁷⁶ and today ELISAs are the principal diagnostic test for rotavirus in stools. ELISAs recognize the rotavirus middle-layer protein VP6 antigen. Reverse transcription polymerase chain reaction (RT-PCR) is more sensitive than ELISA,²⁷² but the extra sensitivity is not usually needed because of the abundance of rotavirus antigen in stools. Usually RT-PCR targets gene segments encoding for VP7 and VP4, the outer capsid proteins applied as the results can also be used for classification.^{78,88} Both ELISA and RT-PCR can be used for detection of rotavirus in serum and whole blood.²⁷ Rotaviruses may still be detected by EM and also by polyacrylamide gel electrophoresis.¹⁰³

TREATMENT

Acute dehydration is the main clinical problem associated with RVGE. A 20-point score (Vesikari score) is commonly used for assessment of clinical severity of RVGE (Table 173.1). A score of 11 of 20 roughly correlates with severity that requires active rehydration therapy. The principles of treatment, oral rehydration, continued feeding, and possibly probiotics, as well as avoidance of drugs, are similar in all forms of gastroenteritis, rotavirus or not.

Reduced-osmolarity oral rehydration solution (224 mOsm/L) (ORS) has been shown to be more effective in RVGE than full-strength (iso-osmolar) ORS as measured by stool output, reduced vomiting, and reduced need for supplemental intravenous therapy²⁰⁶; consequently, ORS with sodium concentration of 50 to 60 mmol/L is recommended as first-line therapy.

TABLE 173.1 Numerical Scoring (1–2+ Points) for Severity of Rotavirus Diarrhea

Duration of Diarrhea (Days)

1–5%	2
≥6%	3
Treatment	
Clinic (oral) rehydration	1
Hospitalization	2
Total	20

From Ruuska T, Vesikari T. Rotavirus disease in Finnish children: use of numerical scores for clinical severity of diarrhoeal episodes. *Scand J Infect Dis.* 1990;22:259–267.

If oral rehydration is not successful, enteral rehydration by the nasogastric route is the next preferred rehydration method even in children with severe dehydration. Enteral rehydration, whether given orally or by nasogastric tube, is associated with significantly fewer major adverse events and a shorter hospital stay than intravenous rehydration. All guidelines state that if the child is breast-fed during the infection, breastfeeding should be continued throughout rehydration.

Probiotics, *Lactobacillus rhamnosus* GG¹⁵⁵ and *Lactobacillus reuteri*,²²⁵ have been shown to significantly shorten the duration of rotavirus diarrhea.

ROTAVIRUS IMMUNITY

Individuals can experience multiple rotavirus infections during their lifetime, but natural rotavirus infection, whether symptomatic or asymptomatic, provides a protective effect against subsequent disease. The severity of rotavirus infections decreases with increasing number of infections, each reinfection broadening and boosting natural immunity.^{17,20,61,184,244,245} The second infection provides practically complete protection against moderate-to-severe disease. Both humoral and cell-mediated immunity contribute to the resolution of ongoing rotavirus infection and protection from subsequent infection.

Immune Responses in Rotavirus-Infected Individuals

Rotavirus infection induces both systemic and mucosal antibody responses. Humoral anti-rotavirus responses include an early IgM response followed by the production of IgG and IgA.^{47,92,214} Local response is considered to be important against rotavirus, as higher titers of intestinal IgA have correlated with protection from rotavirus infection and disease.^{41,161} Of the serum antibody responses, IgA levels have been associated with protection against moderate-to-severe disease.^{85,104,184,245}

Natural rotavirus infection generates antibodies directed against structural as well as nonstructural proteins.^{210,211,232} Only VP4 and VP7

surface proteins are able to elicit classical neutralizing antibodies with type-specific and cross-reactive serotype responses.^{5,31,211} The first rotavirus exposure is believed to induce a primarily homotypic antibody response, which is broadened to heterotypic responses upon recurrent exposure.¹⁸⁴ However, the occurrence of sequential infections even with the same serotype, although less frequent than with different serotypes, indicates that neutralizing antibodies are not sufficient for protective rotavirus immunity.^{82,266,244} VP6 protein plays a role in protective immunity, because the strongest antibody response to rotavirus infection seems to be developed against this inner capsid protein.^{210,211,232} VP6-specific antibodies have been identified as the dominant B-cell response following rotavirus infection in infants and adults.^{267,268}

Cell-mediated immune responses have also been demonstrated after natural rotavirus infection. Because of the difficulty of studying intestinal antigen-specific T cells *in situ* in humans, characterization of T-cell responses has been concentrated on identification of the presence of rotavirus-specific T cells in circulation.^{156,180} Rotavirus-specific CD4⁺ and CD8⁺ T cells have been detected in the circulation of rotavirus-infected and healthy adults,¹¹⁵ but the induced responses appear to be lower or even undetectable in children with RVGE.^{115,216} Chronic rotavirus infection in B- and/or T-cell immunodeficient children⁸¹ indicates the importance of both the cellular and humoral arms of the immune system in the clearance of rotavirus infection.

According to the knockout mouse models, rotavirus-primed memory B cells, and hence rotavirus-specific antibodies, seem to provide more long-term protection against subsequent rotavirus infection, whereas rotavirus-specific T cells help to limit the course of infection.^{71,69,171,169} According to these models, rotavirus-specific CD8⁺ T lymphocytes are efficient in resolution of a primary rotavirus infection.^{50,70,217} These murine cytotoxic T lymphocytes also mediate nearly complete short-term and partial long-term protection against reinfection.⁷² Moreover, the development of protective anti-rotavirus intestinal IgA response is, at least partially, CD4⁺ T-cell dependent.^{70,171,243}

Mechanisms of Protection

Because of the replication site of rotaviruses in intestinal enterocytes, effector mechanisms are assumed to be active at the intestinal mucosa. The majority of circulating rotavirus-specific B cells and CD4⁺ T cells express intestinal homing receptors, indicating trafficking of primed cells to the intestine for local action.^{86,216,268}

The most evident effector is secretory IgA (SIgA), which is produced following polymeric immunoglobulin receptor-mediated transcellular transport of polymeric IgA (pIgA) across the epithelial cells into the gut lumen. As in humans, evidence of the role of SIgA is supported by the correlation of protection against rotavirus infection in mice and piglets with the levels of rotavirus-specific intestinal and serum IgA.^{57,170,239} However, it has been shown that rotavirus-specific IgG or IgM in the gut or in sufficient amounts in serum can reach the intestine and mediate protection in IgA-deficient individuals.^{112,183}

The protective nature of antibodies directed to VP4 and VP7 is based on the ability of these antibodies to neutralize rotavirus classically

by inhibiting viral attachment to the cell or decapsidation.^{63,149} Passive transfer of neutralizing VP4- and VP7-specific antibodies has been demonstrated to clear rotavirus infection in suckling mice.^{162,181}

Antibodies directed against VP6 are generally considered nonneutralizing, but several studies have demonstrated inhibitory activity of anti-VP6 antibodies against rotavirus infection *in vitro*.^{1,2,75,135} Moreover, certain VP6-specific pIgA antibodies have been shown to be capable of preventing and clearing a chronic murine rotavirus infection.²⁸ These antibodies appear to contribute protection by mediating antiviral function via intracellular neutralization.^{40,58} The intracellular neutralization of rotavirus have recently been described to result from inhibition of rotavirus transcription during the transcellular transport of anti-VP6 pIgA antibodies via binding of these antibodies into the type I channel, thus blocking egress of RNA from the DLP.¹

ROTAVIRUS VACCINES

Live attenuated rotavirus vaccines are given orally to multiply in the intestines and induce immunity mimicking that after natural rotavirus infection. The two major licensed rotavirus vaccines in the free market are a human rotavirus G1P[8] “monotypic” vaccine (Rotarix) and bovine-human reassortant “pentavalent” rotavirus vaccine (RotaTeq). These generic names are misleading and do not reflect their protective efficacy across human group A rotavirus types, whether included in the vaccine or not.

Other rotavirus vaccines are licensed in China,⁷³ India, and Indonesia (Table 173.2), and still others are being developed. Historically important are bovine rotavirus (heterologous) vaccine and rhesus rotavirus vaccine with its reassortants (RotaShield), which became the first licensed rotavirus vaccine but was withdrawn because of association with intussusception (IS). IS is still casting a shadow on all live oral rotavirus vaccines.

Bovine rotavirus strain RIT4237 (G6P[5]) was the first rotavirus vaccine tested in humans. The vaccine is highly attenuated with a history of 154 cell culture passages, much more than any other rotavirus vaccine strain. The adaptation to cell culture resulted in growth to a high titer over 10⁸ TCID₅₀/mL,⁴⁸ which is higher than in the present oral vaccines and may explain the good efficacy of this vaccine in the early trials in Finland. In its first efficacy trials in 1983, a single dose of RIT4237 vaccine induced 50% protection against any and 88% protection against severe (“clinically significant”) rotavirus disease,²⁴⁸ a result that remains a benchmark for other vaccines and trials. Two doses of the same did not improve efficacy.²⁴⁹ In Peru the efficacy was 40% against any and 75% against severe RVGE,¹³³ and in Gambia the efficacy was 33% but severity of RVGE was not measured.⁹⁸ Thus, a gradient of efficacy between developed and developing countries was observed, as has later been seen with other rotavirus vaccines.

The higher efficacy of rotavirus vaccine against severe rotavirus disease was also documented using the 20-point score (see Table 173.1).^{220,219} The same score has since been applied to measure efficacy of the other rotavirus vaccines; an example for RRV-TV is shown in Fig. 173.3.

TABLE 173.2 Licensed Live Oral Rotavirus Vaccines

Vaccine	Strain(s)	Developer/Manufacturer	Status in Development
Single-Strain Human Rotavirus Vaccines			
Rotarix	Human strain G1P1A[8]	GlaxoSmithKline (Belgium)	Licensed worldwide
Rotavac	Human neonatal strain 116E G9P[11]	Bharat Biotech International Limited (India)	Licensed in India
Rotavin-M1	Human strain G1P1A[8]	Polyvan (Vietnam)	Licensed in Vietnam
RV3-BB	Human neonatal strain G3P2A[6]	Murdoch Childrens Research Institute (Australia) and Biofarma (Indonesia)	Phase III trial
Animal-Human Reassortant Vaccines			
RotaShield	Tetavalent human-rhesus reassortant G1-G4 + P7[5]	Wyeth (US)	Withdrawn 1999, Phase II trials of neonatal administration in Ghana
RotaTeq	Pentavalent human-bovine reassortant G1-G4 + P7[5]; G6 + P1A[8]	Merck (US)	Licensed worldwide
LLR	Lamb rotavirus strain G12P[10] ¹⁴¹	Lanzhou Institute of Biological Products (China)	Licensed in China

FIG. 173.3 Efficacy of RRV-TV (RotaShield) against rotavirus gastroenteritis of different severity as assessed using the Vesikari score. (From Joensuu J, Koskenniemi E, Pang XL, et al. Randomised placebo-controlled trial of rhesus-human reassortment rotavirus vaccine for prevention of severe rotavirus gastroenteritis. *Lancet*. 1997;350:1205-1209.)

The RIT4237 vaccine was withdrawn from further development for a combination of reasons. However, the series of studies of this bovine rotavirus vaccine established many general principles that were largely confirmed later for other oral rotavirus vaccines: (1) a higher titer of oral inoculum resulted in greater immune response²⁵⁹; (2) rotavirus vaccine virus was sensitive to gastric acidity, and buffering of the vaccine or milk feeding was needed for successful vaccine uptake²⁵⁰; and (3) breast milk or breastfeeding did not suppress the uptake to any significant degree, especially if the titer of vaccine was high.^{259,260} Early studies also showed that concurrent administration of oral polio vaccine (OPV) suppresses the uptake of bovine rotavirus vaccine, whereas rotavirus vaccine had only minimal inhibitory effect (interference) on OPV.^{80,264}

WC-3 Bovine Rotavirus Vaccine

WC-3 stands for Wistar Calf according to the Wistar Institute, where the vaccine was developed.³⁵ This bovine G6P[7] rotavirus strain is less adapted to cell culture (about 20 passages) and therefore grows only to a titer of approximately 10^7 PFU/mL. In the main US efficacy trial, the WC3 vaccine yielded only 20% protection against RVGE and was not developed further.¹⁸ However, the strain is the backbone for bovine-human reassortants that are included in the current “pentavalent” (RV5) bovine-human reassortant rotavirus vaccine.

Rhesus Rotavirus (RRV) Vaccine

Rhesus (monkey) rotavirus strain (G3P[5]) was grown 9 times in monkey kidney and 7 times in fetal rhesus lung cells and adopted as human vaccine.¹²³ Unlike bovine rotavirus vaccine, RRV is clearly virulent in humans by causing fever, though not diarrhea.²⁵² At a high titer level of 10^5 PFU/dose the RRV vaccine was efficacious but reactogenic.^{67,87} Importantly, however, RRV served as a backbone for the development of the rhesus-human reassortant vaccines,¹⁷³ of which the tetravalent composition (RRV-TV) became the first licensed rotavirus vaccine in 1998.

Rhesus-Human Reassortant Vaccine

Rhesus-human reassortant tetravalent (RRV-TV) vaccine (RotaShield, Wyeth) is the prototype of reassortant vaccines and contains four viruses expressing human G1, G2, and G4 VP7 antigens on the rhesus G3P[5] rotavirus genetic backbone plus the RRV itself. RRV-TV retained the high reactogenicity for fever of RRV. RotaShield vaccine was in use in the United States in 1998–99, but was withdrawn because of association with IS.^{178,227}

RRV-TV is a more efficacious vaccine than the parent rhesus rotavirus vaccine.²⁰⁹ In the pivotal efficacy trials before licensure of RotaShield, the RRV-TV vaccine showed an efficacy of 100% against hospitalization for RVGE and 68% against any RVGE in Finland¹²⁰ and 75% and 48%, respectively, in Venezuela.¹⁹⁷ These results were instrumental for wider acceptance of protection against severe RVGE as the primary endpoint of rotavirus vaccine efficacy. Lower vaccine efficacy in developing

FIG. 173.4 RotaTeq composition.

countries was also accepted with the understanding that rotavirus vaccination could still prevent a large number of severe RVGE cases.

RotaShield vaccine was withdrawn in 1999 in the United States because of association with IS, before it was launched in Europe or tested in developing countries. Recently, RRV-TV, given to neonates to minimize risk of IS, was tested in Ghana with promising results, and the possibility of reintroduction in developing countries remains viable.⁶

Bovine-Human Reassortant Vaccine

The “pentavalent” bovine-human reassortant rotavirus vaccine (RotaTeq, Merck; also termed RV5) was licensed in 2006 and is one of the two major rotavirus vaccines used globally. The vaccine is a combination of four G-type reassortants (for G1–G4) and one P-type (P[8]) reassortant on the WC-3 bovine rotavirus genetic backbone (see Fig. 173.3).³⁶ The terms pentavalent or RV5 refer to the five mono-reassortants present in the vaccine. However, it is now well established that the protection induced by the vaccine is not limited to the G or P types contained in the product. The vaccine is given in three doses. This was determined early on to accommodate the US childhood immunization program, but was also based on the demonstration of incremental immunogenicity up to the third dose.^{33,34,247}

The efficacy and safety of RotaTeq vaccine were established in a large trial (70,000 infants) known as REST (Rotavirus Efficacy and Safety Trial). The overall efficacy against health care utilization (combined endpoint of hospital admission and outpatient clinic treatment) was about 95% with a narrow confidence interval.^{251,258} An extension study of REST in Finland of 21,000 children confirmed that RotaTeq was efficacious not only against G1, G3, and G4, all P[8], and the heterologous P-type G2P[4], but also against G9P[8], which is not among the G-types in the vaccine.²⁵³ In Japan the efficacy of RotaTeq was similar to that in the United States.¹¹⁴ In Ghana and Kenya, the efficacy of RotaTeq was lower (64% and 83%, respectively) than in the United States or Europe.⁷ In Asian developing countries, a point estimate of 45% was found.²⁷⁷

The G1 and P[8] reassortants included in RotaTeq vaccine (Fig. 173.4) may re-reassort with each other and form vaccine-derived (vd) double reassortants on the bovine rotavirus VP6 core.^{51,102} vdG1P[8] viruses may be more virulent than the original single reassortant vaccine viruses, and they may be responsible for the low rate (about 1%) of diarrhea seen after vaccination. They may also be capable of transmission.¹⁹⁶ If transmitted to immunocompromised subjects, the vaccine viruses may cause prolonged infection.¹⁹⁰ Shedding of live infectious virus after the first dose of vaccination was found in about 9% in the REST study, but using RT-PCR shedding may be found in about 50% of the recipients, with G1 reassortants being the most common.¹⁵⁸

UK-bovine rotavirus strain is another platform for reassortment.²⁵⁶ However, development of UK-bovine tetravalent (G1–G4) reassortant vaccine was discontinued by Wyeth at the same time as the RotaShield vaccine was withdrawn. The technology has been licensed (by the US National Institutes of Health) to several manufacturers in India, China, and Brazil, but none of the vaccines have yet been licensed.

Human Rotavirus Vaccines

Rotarix

Human rotavirus vaccine RV1 (Rotarix, GSK, also termed RV1) was licensed in 2006 and is the most extensively used rotavirus vaccine today. It was derived from a G1P[8] rotavirus isolate in Cincinnati, passaged 33 times in cell culture, and designated 89-12.¹⁶ The strain was acquired by GSK, cloned (by plaque purification), and passaged another 12 times in MRC-5 cells. In this process the virus lost its residual reactogenicity and is generally regarded as nonreactogenic for humans.²⁵⁵ The titer of the vaccine chosen for the final formulation is about 10^5 PFU/dose, although the virus could be grown to a one-log higher titer.²²² Rotarix multiplies effectively in humans, as characterized by a high rate of shedding (60% or even more) after the first dose, but does not cause diarrhea.²⁵⁵

Rotarix is given in two doses. The uptake and immunogenicity are excellent (90%) even after the first dose when given in the presence of a low level of maternal antibody. The second dose under such circumstances does not add much, but the uptake is prevented by the immunity induced after the first dose, as indicated by the lack of shedding and lack of booster.²⁵⁵ The pivotal safety and efficacy trial for licensure was carried out in 60,000 children in Latin America²¹⁸ and efficacy determined in a subset of 20,000 infants. Two endpoints were used: need for (oral) rehydration and score of 11 out of 20. Both yielded approximately 85% efficacy in 1-year follow-up.²¹⁸ In addition, before licensure in Europe, the vaccine was tested in five European countries and later in Japan¹²⁷ with similar results. In Europe, the follow-up was for two rotavirus seasons and the primary endpoint was severe RVGE as defined by a score of 11/20. Against this endpoint, efficacy for 2 years was 91%, with 96% efficacy in the first season and 86% in the second season, suggesting some decline over time. Against any RVGE, efficacy was 78% and 68% in the first and second year, respectively, for a total of 72% over 2 years. Furthermore, against severe RVGE on 2 years of follow-up, the efficacy for various G-types was similar, ranging from 96% for G1P[8] to 86% for G2P[4]; the differences were not statistically significant.²⁵⁷ Evidence from Asia indicates that protection is sustained into the third year of life.¹⁹⁹

Rotarix and RotaTeq have not been tested head-to-head for efficacy in any trial. On the other hand, both vaccines have been tested for efficacy in different environments, from developed to “intermediate” to developing countries, and the results of such studies can be compared with each other (Fig. 173.5A). In South Africa and Malawi, the efficacy of two doses of Rotarix against severe RVGE (score of 11 out of 20) was 61.2% and 49.4%, respectively, in 1-year follow-up.¹⁵³ Also in these African countries, there was no difference in vaccine efficacy against G1 and non-G1 (G2, G8, G12) rotaviruses.¹⁵⁴

Other Human Rotavirus Vaccine Strains

(See Table 173.2.) Another human rotavirus vaccine has been prepared from a G1P[8] rotavirus isolate in Vietnam and designated as “Rotavin.”¹⁴⁶ This vaccine is licensed in Vietnam.

RV3 is based on a neonatal G3P[6] rotavirus strain from Melbourne. A Vero cell adapted derivative of the strain, called RV3-BB, grows to a higher titer and is more immunogenic than the original RV3.⁴⁴ The vaccine will be manufactured in Indonesia and is undergoing a phase III trial.

The rotavirus 116E is an Indian neonatal strain of genotype G9P[11]. Natural attenuation of the neonatal strain by a modified P-antigen (VP4 gene of bovine origin) was regarded as an advantage in the selection of this strain as a candidate vaccine.⁴⁵ The efficacy of 116E against severe RVGE in a trial in India was about 55% for three doses,¹⁹ and the vaccine (Rotavac, Bharat Biotech) is now licensed in India and is being introduced into the National Immunization Program (NIP) of India.

Immune Response and Mechanism of Action

Total rotavirus serum IgA antibody has been the most widely used immunologic marker for uptake of rotavirus vaccine. From studies on consecutive wild-type rotavirus infections, it is known that a high titer of serum rotavirus IgA antibody correlates with protection.^{266,245} This can be applied to vaccine-induced immunity as well. High serum IgA responses are consistently induced by efficacious rotavirus vaccines such as Rotarix and RotaTeq, and it is logical to assume that serum IgA-mediated immunity is not only a surrogate marker¹⁸⁹ but also an actual mechanism of rotavirus vaccine-induced protection against severe rotavirus disease.

Wild-type rotavirus infections induce neutralizing antibodies against the rotavirus surface antigens VP7 and VP4, which protect against subsequent infections by the same serotype. Such antibodies are also induced after vaccinations, but the responses are inconsistent and the antibody levels often low.²⁴⁶ Rotavirus vaccines do not induce much protection against rotavirus infection, and it is unlikely that these neutralizing antibodies are a major mechanism of action that reduces the severity of RVGE, although they may play some role in vaccine-induced protection. For both Rotarix and RotaTeq, G1-specific neutralizing antibody response and protection against G1 strains may be dominant.

G-type specific immunity induced by the vaccines may also “protect” against the homologous vaccine virus, that is, the subsequent dose of the vaccine itself. This is clearly seen by the lack of a booster effect to a monospecific human G1P[8] vaccine²⁵⁵ and RRV.²⁰⁹ The second dose of RV1 only “takes” if the first dose has not taken. Giving three or even five doses of monovalent human rotavirus vaccine does not much improve the uptake of this vaccine in developing countries.¹³⁰ In contrast, the reassortant vaccines may have an advantage of multiple doses “taking,” as it is unlikely that all reassortants succeed in taking upon the first dose. A second and third dose of the “multivalent” vaccine may have a better opportunity of taking and inducing a booster effect, that is, an increase of rotavirus IgA serum antibody level.

In a recent study of mixed administration schedules of rotavirus vaccines in the United States, three doses of RotaTeq was clearly more immunogenic overall (rotavirus IgA response) than two doses of

FIG. 173.5 Representative efficacy point estimates against severe RVGE with score of 11 out of 20 of RV5 and RV1 in (A) prelicensure trials and (B) postlicensure real-life effectiveness studies for RVGE hospitalizations in different geographic areas.

Rotarix.¹⁴² All neutralizing antibody responses were broader after RotaTeq. The same study showed that replacing one dose of RotaTeq with Rotarix may actually be advantageous. The strongest rotavirus IgA response occurred when one dose of Rotarix was followed by two doses of RotaTeq.

The target antigen of serum rotavirus IgA is largely the rotavirus inner core protein VP6. VP6 is a strong immunogen, and immune responses to it overshadow those to other structural rotavirus antigens.^{232,233} Anti-VP6 antibodies are “nonneutralizing” in the sense that they do not prevent rotavirus infection *in vitro* or *in vivo* (see earlier discussion). However, intracellularly acting anti-VP6 IgA antibodies block the infection at a later stage and, conceivably, may protect against rotavirus disease.⁴⁰ A plausible mechanism of the intracellular action may be that the anti-VP6 antibodies stabilize the VP6 inner core particle and prevent it from releasing rotavirus RNA.¹ An intracellular mechanism of effect is also consistent with the concept of rotavirus vaccines protecting against disease rather than infection.

Comparative Efficacy

In general, the overall and serotype-specific efficacies against severe RVGE of the two vaccines are remarkably similar, but depend on the environment.

Real Life Effectiveness

A recent review has addressed both the difference between developed (high-income) and middle-income countries as well as the lack of serotype specificity in protection against severe RVGE in postlicensure effectiveness studies.¹³⁹ The gradient between developed and developing countries that was found in prelicensure studies is seen also in postlicensure real-life effectiveness studies. Some representative examples of the point estimates are shown in Fig. 173.5B.

In Europe, the examples of Finland and Belgium are well representative, showing over 90% effectiveness for hospitalization with RVGE over some period of time in countries that have reached a high coverage with RV5 (Finland) and RV1 (Belgium), respectively.²⁶ In the United States, the 4-year follow-up of Payne et al reported 84% effectiveness for RotaTeq.¹⁹⁵ In Brazil, representing Latin America, the point estimate of effectiveness is of the order of magnitude 80%.^{39,122} In South Africa, effectiveness of 57% was reported.⁹⁴

Serotype (Genotype) Specific Effectiveness

The postvaccination experience confirms the finding in prelicensure studies that rotavirus vaccine effectiveness against severe RVGE is not strain specific and the terms “monovalent” for RV1 and “pentavalent” for RV5 are not functionally appropriate. Instead, these acronyms should only be used to refer to the number of constituents in each vaccine.

Although some serotype replacement of circulating rotaviruses has happened, new rotavirus serotypes have not permanently replaced old ones, and rotavirus vaccines have remained effective against severe RVGE associated with all circulating rotavirus strains. Soon after introduction of Rotarix vaccine in Latin America the G2P[4] rotaviruses became dominant among the RVGE cases, but Rotarix G1P[8] vaccine remained effective against severe RVGE caused by this G type.^{39,122} Rotavirus G type G3P[8] has possibly become more common after introduction of RV5 vaccine in Finland and the United States, but it has never gained predominance.^{101,195} G12P[8] has emerged in the United States and elsewhere, but has not remained predominant either. Recently, even more diversity of rotavirus genotypes has been observed in Finland, but total rotavirus activity has remained low.¹⁵⁹

Impact of Rotavirus Vaccination: Direct and Indirect

The US experience shows that RVGE cannot be eliminated at a vaccine coverage of 75% to 80%, but rotavirus epidemics have occurred biannually instead of every year.¹⁹⁵ More generally, the impact of universal rotavirus vaccination cannot be reliably measured by short-term follow-up only. The first large-scale introduction of rotavirus vaccination will likely break the transmission chain of the wild-type rotavirus with resulting short-term direct and indirect impact, but rotavirus disease activity will resurge later.

The impact of rotavirus vaccination in early introducing European countries was recently reviewed by Karafillakis et al.¹²⁵ In Austria, with

coverage of 72% to 74%, the reduction of RVGE hospitalizations in the target age group was 81% to 84% and remained sustained up to 3 years. However, while there was initially an indirect effect on unvaccinated children as well, after 3 years this was followed by an increase of RVGE hospitalizations in 5- to 14-year-old children. In Belgium, with a coverage rate of 90%, the direct impact on RVGE hospitalization in the target group has been about 80% and the 3-year indirect effect in older children 20% to 64%. In Finland, with rotavirus vaccination coverage of 95% to 97%, the reduction in cases of RVGE seen in hospitals was 94% in a period of 4 years after vaccination, but specifically in age group 5 to 14 years, no significant reduction has been seen over this period. Actually, the direct impact in the target age group of rotavirus vaccination has shifted the occurrence of RVGE to older unvaccinated children¹⁰¹ and adults.¹⁵⁹

It may be concluded that although higher coverage results in greater impact of rotavirus vaccination on severe RVGE, even very high coverage does not lead to elimination of RVGE through herd protection. Rotavirus vaccination has had a clear impact on rotavirus disease in all age groups, as reported from the United States,^{76,145} but it remains to be seen whether this effect is durable over time.

Introduction of Universal Rotavirus Vaccination

The first country to introduce universal rotavirus vaccination was Brazil in March 2006, followed soon by Venezuela and Mexico, and about 20 more Latin American countries using Rotarix vaccine. Universal recommendation for RotaTeq vaccine was issued in the United States soon after licensure in 2006.¹⁸⁶ Other early introducers were Australia (both vaccines) and South Africa (Rotarix) since 2009.

In Europe, Austria (both vaccines) and Belgium (Rotarix) were the first introducers in 2007, followed by Finland (RotaTeq exclusively) in 2009. After that, there was a gap of a couple of years until Germany started vaccinations state by state. The most significant step forward is perhaps the UK introduction, and effective implementation, in 2014.⁸

Globally, the most significant recent progress has been introduction of rotavirus vaccination in Africa since 2013, made possible by support from GAVI. The true impact of these programs can only be assessed after several years, although the first results appear promising. With the exception of Rwanda, all African countries have introduced Rotarix vaccine.

Eight of the 10 countries with the highest mortality from RVGE are in Asia,^{126,234} and none of these countries have yet implemented universal rotavirus vaccination. India has announced a program using the locally produced Rotavac, and the Philippines has a government program for the poorest section of the population.

Rotavirus Vaccine Recommendations

Before rotavirus vaccine introduction and also apart from universal vaccination programs, national recommendations for rotavirus vaccination have been issued in many countries. A crucial one was the US Advisory Committee on Immunization Practices (ACIP) recommendation that was issued immediately after licensure of RotaTeq.¹⁸⁶ Globally, the most important one is the World Health Organization (WHO) position and universal recommendation.²⁷¹ In Europe, there is no formal recommendation-issuing body, but the pediatric societies ESPID and ESPGHAN issued recommendations in 2008 that were updated as ESPID recommendations in 2015.²⁶²

All major recommendations have held that rotavirus vaccination should be given to all children, simply because no special “risk groups” for RVGE can be reliably identified. Vaccination of special groups is a separate issue discussed next.

Special Target Groups and Issues

Prelicensure efficacy trials of rotavirus vaccine were conducted in healthy infants and had many exclusion criteria. Therefore, knowledge on safety and efficacy of rotavirus vaccine in many special groups has accumulated slowly.

Premature Infants

Both RotaTeq and Rotarix, as well as RotaShield,²⁵⁴ vaccines can be given to prematurely born infants regardless of gestational age, but

following the recommendations according to calendar age.^{89,182,230} If the infant is still in the hospital, a possible risk of local transmission of vaccine virus must be considered.

HIV-Infected Children

Asymptomatic HIV-infected infants can be vaccinated normally according to calendar age without any safety issues using either Rotarix²²⁹ or RotaTeq.¹³⁶ Screening for maternally acquired HIV infection can often be done by the time of rotavirus vaccination at 6 to 8 weeks of age, but the result is not needed for decision making on rotavirus vaccination.²⁶²

Immunodeficiency

Rotavirus vaccine causes symptomatic disease (prolonged diarrhea and viral shedding) in children with severe combined immunodeficiency.^{11,270} Vaccination is therefore contraindicated, and exposure to rotavirus vaccine shedders should be avoided in such children. Other immunodeficiencies may be regarded similarly. Selective IgA deficiency may result in prolonged shedding of rotavirus vaccine, but does not constitute a safety problem and, in any case, is usually not diagnosed by the time of rotavirus vaccination.²⁶²

Short Gut Syndrome and Intestinal Failure

Young children with intestinal failure are at risk for complications from RVGE and should therefore be considered for rotavirus vaccination. Two recent studies have shown that rotavirus vaccine may cause substantial symptoms in such children, but given the severity of wild-type rotavirus infection, they should nevertheless be vaccinated under close observation.^{56,117}

Breastfeeding

Early studies with bovine and rhesus rotavirus vaccines showed little or no reduction of vaccine uptake in breast-fed infants compared with bottle-fed infants.^{30,260} The question of possible suppressive effect of breastfeeding is largely theoretical, as there is no question of recommending against breastfeeding for the uptake of rotavirus vaccination. Specifically, it has been shown that a break in breastfeeding at the time of rotavirus vaccine administration does not increase uptake.⁹³

Influence of Oral Polio Vaccine

The early studies of bovine rotavirus vaccine administered with OPV showed that OPV suppressed the uptake of rotavirus vaccine but not vice versa.^{80,264} The subject was recently reviewed by Patel et al with the same conclusion.¹⁹¹ Rotavirus vaccines do not adversely affect OPV immunogenicity, but OPV does interfere with the uptake of (at least) the first dose of rotavirus vaccine. Also, rotavirus IgA antibody levels remain lower after a course of two doses of Rotarix or three doses of RotaTeq when administered concomitantly with OPV.¹⁹¹

To avoid interference, spacing of OPV and rotavirus vaccine (at least for the first dose) would be desirable.²⁶² This must be balanced against programmatic needs. In Latin America, Rotarix was coadministered with OPV and showed high efficacy.²⁴⁰

If OPV suppresses/prevents the uptake of the first dose of Rotarix, the second dose 2 months later may become effectively the first dose. This could explain why a small risk of IS after the second dose of Rotarix was identified in Brazil but not in Mexico.¹⁹²

Intestinal Microflora

Composition of microflora may reduce the uptake of rotavirus vaccine in developing countries. It would be important to find ways to modulate the microflora for more optimal conditions for rotavirus vaccination, but no such intervention (e.g., probiotics) is proven as yet.

Intussusception

IS is the most important adverse effect of rotavirus vaccination and has already caused the withdrawal of the first licensed rotavirus vaccine, RotaShield, from the market. IS occurred mostly 3 to 7 days after the first dose of RotaShield, and the attributable risk was estimated at 1:10,000.¹⁷⁸ This rate was later challenged and a rate of 1:32,000 was proposed instead.²²⁷ Furthermore, the risk of IS was shown to be age

dependent, as most of the cases occurred in the catchup vaccination program in infants who were over 90 days of age at the time of the first dose.²²⁷

It is now well established that both of the leading licensed rotavirus vaccines, Rotarix and RotaTeq (and most likely other live rotavirus vaccines as well) are also associated with IS. This could not be detected in prelicensure trials that were designed to rule out a risk of IS of similar magnitude as that of RotaShield. Later, in prospective surveillance studies after the launch, the risk estimates of IS for both vaccines are between 1:50,000 and 1:80,000, and the relative risks over background of both vaccines in the 7-day period after dose 1 are about 5.⁹⁵

The small risk of IS is often weighed against the benefits of rotavirus vaccination, and this comparison comes out in favor of vaccination in most settings.²⁷¹

Although it is not currently known whether the risk of IS associated with the currently licensed rotavirus vaccines follows the same age-related pattern as that of RotaShield, it seems logical to assume that this is the case. It may be prudent to follow the current ESPID recommendation and give the first dose of rotavirus vaccine as early as possible, that is, at 6 to 8 weeks of age.

Porcine Circovirus

In 2010 both licensed rotavirus vaccines were found to have porcine circovirus (PCV) as contaminants.^{168,263} This created some concern, although PCV is not known to infect humans, and the WHO and European Medicines Agency held that rotavirus vaccines may continue to be used. In Rotarix, PCV contamination was traced to virus seed, and the manufacturer is committed to provide a PCV-free vaccine in the future. In RotaTeq, the source of contamination was traced to batches of trypsin used in the manufacturing process,²⁰⁴ and with changes in the process, PCV-free vaccine should be available.

Nonlive Rotavirus Vaccines

The need and rationale for the development of nonlive rotavirus vaccines as alternatives for live oral rotavirus vaccines are based on efficacy and safety concerns. All live rotavirus vaccines have shown a relatively (in comparison with developed countries) low efficacy in developing countries for reasons that may not be easily remedied, and repeated parenteral (or possibly intranasal) immunization might induce a high level of protection bypassing the intestinal obstacles. IS remains a serious safety concern, although the magnitude of the problem is regarded as tolerable. This may, however, change. Also, the possibility of contamination by adventitious agents such as PCV is limited to live vaccines.

Nonlive rotavirus vaccines might be administered mucosally or parenterally. The types of vaccines under consideration include three main categories:

1. Inactivated whole rotaviruses¹¹⁹
2. Rotavirus virus-like particles (VLPs) of double-layered (VP2/VP6) or triple-layered (2/6/7 or 2/4/6/7) composition^{9,10,25,53,111,215}
3. Recombinant rotavirus proteins such as VP8²⁶⁹ or VP6²²

The only nonlive rotavirus vaccine that has reached human trials is the P-2 VP8* subunit vaccine in which VP8* from G1P[8] virus has been expressed in *Escherichia coli* and fused with P2 T-cell epitope of tetanus toxin to enhance immunogenicity.²⁶⁹

Under appropriate conditions,¹³⁸ rotavirus VP6 alone forms large tubular structures that are strong immunogens. VP6 is also the simplest possible rotavirus candidate vaccine, consisting of only a single protein, which is a group antigen common to and largely conserved among all group A rotaviruses. Rotavirus VP6 vaccine has been shown to protect against live rotavirus challenge in a mouse model.¹³⁵

SUBSECTION IV RNA—Togaviridae

Rubella Virus

174

James D. Cherry • Amira Baker

Rubella (i.e., German measles) is a generally mild, exanthematous, infectious illness that usually causes minimal morbidity and mortality in children. However, infection during pregnancy can result in fetal infection, which usually is associated with considerable adversity for the developing infant. The rubella virus has only one known type.

HISTORY

In ancient history, rubella as a disease is lost among the other prominent exanthematous diseases such as scarlet fever, measles, and smallpox. In an extensive review, Griffith²³⁴ suggested that rubella was known to the early Arabian physicians under the name *al-hamikah*, but they considered rubella a form of measles. Two German physicians, de Bergen in 1752 and Orlow in 1758, usually are credited with providing the first clinical descriptions of rubella as a specific entity.^{234,623} In early writings, rubella was called *Röteln*.^{187,623} However, because of the great interest of German physicians in the disease during the period from the mid-18th to the mid-19th centuries, the name *German measles* frequently was used in other countries.

In 1866, a Scottish physician named Veale⁶⁰⁰ described 30 cases of German measles. In his paper, he gave the illness its present name, *rubella*. His opinion was that the German name *Röteln* was too harsh and foreign and that other possible names—*rubeola notha* and *rosalia idiopathica*—were too long for general use and could be confused with measles.¹⁸⁷ Other historical synonyms for rubella are *rubeola*, *rubeola sine catarrho*, *rubeola epidemica*, *rubeola morbillosa*, *rubeola scarlatinosa*, *rosania*, *roseola*, *roseola epidemica*, *rosalia*, *scarlatina morbillosa*, *scarlatina hybrida*, *morbilli scarlatinosi*, *feuer masern*, *roséole*, *roséole idiopathique*, *rubéole*, *rougéole fausse*, French measles, false measles, bastard measles, hybrid measles, and bastard scarlatina.²³⁴

In 1881, at the International Congress of Medicine in London, a consensus was reached that rubella was a distinct disease. Rubella was thought to be similar in some respects but not identical to measles or scarlatina. By the beginning of the 20th century, the clinical description of rubella was complete, except that joint manifestations had received curiously little description.^{16,130,187,234,384,499,584}

Rubella gained its current importance in 1941, when Gregg,²³³ an Australian ophthalmologist, reported congenital defects in infants of mothers who had rubella during early pregnancy. Despite considerable skepticism, Gregg's observations were confirmed quickly by Swan and colleagues^{563,564} in Australia and other investigators in the United States and the United Kingdom.^{168,473,480,623} By 1947, 28 communications describing 500 children with severe congenital defects associated with maternal rubella had appeared in the literature.⁶²³

In 1938, Hiro and Tasaka²⁷⁴ demonstrated that rubella was caused by a virus transmitted to humans through the subcutaneous injection of filtered nasal washings. In 1942, Habel²⁴² infected monkeys with nasal washings and blood from human cases. In 1962, the rubella virus was propagated in the laboratory by two investigative teams, Weller and Neva⁶²² and Parkman and colleagues,⁴³⁴ who used different techniques and reported the growth of rubella virus in tissue culture.

The isolation of rubella virus in 1962 paved the way for definitive study of the 1964 rubella pandemic.^{358,422,606} The results of extensive virologic, serologic, and epidemiologic investigation were presented at a Rubella Symposium in May 1965.³²⁶ After the rubella virus was isolated in tissue culture, an intensive worldwide effort to develop vaccines was mounted. The accumulation of these experiences resulted in an extensive body of knowledge related to rubella and rubella immunization that was presented at the International Conference on Rubella Immunization in February 1969.³²⁷ Live attenuated rubella virus vaccines were licensed

for use in mid-1969 in the United States.^{328,383,470} In the 46-year period since vaccine licensure and its universal use in the United States occurred, the yearly occurrence of rubella fell from 40,000 cases to 11 cases in 2005.^{79,80,78,84,82,84,457,469,629} During the next decade, the number of cases remained low.^{86,89,334,431} Sustained transmission of rubella no longer occurs in the United States.^{83,468}

PROPERTIES

Classification

Rubella virus is placed in the *Rubivirus* genus of the family *Togaviridae*.^{178,275,330} It is the only species in this genus. The virus is similar physiochemically to the other member of its family (i.e., alphavirus) but is unrelated serologically. Rubella virus has no invertebrate host, which is a characteristic of all alphaviruses, and humans are the only known vertebrate host.

In 2005, the World Health Organization (WHO) adopted a systematic nomenclature to categorize the distinct genetic variants of rubella virus. Rubella virus genotypes were divided into two phylogenetic groups, clade 1 and clade 2, which have an 8% to 10% difference at the nucleotide level. This was updated in 2013 to upgrade three provisional genotypes, with 1a as the last remaining provisional genotype. Clade 1 includes 10 genotypes (i.e., 1a, 1B, 1C, 1D, 1E, 1F, 1G, 1H, 1I, and 1J), and clade 2 includes 3 genotypes (i.e., 2A, 2B, and 2C). Recognized genotypes are denoted with uppercase letters, in contrast to provisional genotypes that are designated with lowercase letters. Of these 13 genotypes, only 4 (i.e., 1E, 1G, 1J, and 2B) are repeated frequently in global distribution.⁶⁴¹ This classification has been especially important in the WHO's virologic surveillance and has greatly aided elimination efforts.^{1,429,431,639}

Physical Properties

The rubella virion is spherical, with a diameter of 60 to 70 nm. It consists of a capsid protein (C) and two glycoproteins (E1 and E2).^{96,275,346,366,443} E1 has a relative molecular weight of 58,000 daltons, and E2 has a relative molecular weight of 42,000 to 47,000 daltons. They are glycosylated and located on the viral surface membrane. E1 is the viral hemagglutinin that is found on 5- to 6-nm surface projections.^{278,443} The nucleocapsid has a diameter of 30 to 40 nm and is composed of a polypeptide (i.e., C protein) and the genomic RNA. The nucleic acid of rubella virus is single-stranded RNA with a molecular weight of 3.2×10^7 daltons and a genome of 9762 nucleotides.⁵¹⁷ Its genome encodes five protein products, including two nonstructural proteins (i.e., P90 and P150) and three virion proteins (i.e., C, E1, and E2). The outer coat of the virus (i.e., envelope) is lipoprotein with host cell lipid and virus-specified polypeptides.

Rubella virus is relatively sensitive to heat; it can lose infectivity within 30 minutes at 56°C (132.8°F).^{174,435,448} However, Kistler and Sapatino³¹⁷ observed that some infectivity persists even after heating for 60 minutes at 70°C (158°F). At 37°C (98.6°F) in the presence of 2% serum, 90% of virus is inactivated in 3 hours.⁴³⁵ At 4°C (39.2°F) with protein stabilization, viral titers are maintained for 7 or more days. The virus is stable indefinitely at -60°C (-76°F) and below but labile at normal (-10°C to -20°C [14°F to -4°F]) refrigeration temperatures. When it is stabilized with protein, the virus can survive several rapid freeze-thaw cycles without significant loss of titer.⁵⁰²

Rubella virus is sensitive to ultraviolet light. In 1 hour, a high-titer, cell-free virus suspension was inactivated by an intensity of 1350 μW/cm²; however, a tissue culture suspension of virus was not inactivated completely when it was exposed to a similar intensity of radiation.³¹⁷ Rubella virus is sensitive to visible light, and photosensitivity can be potentiated by the basic dye proflavine.⁴⁹

The virus also is sensitive to pH extremes of less than 6.8 and greater than 8.1.⁹³ Several chemicals rapidly inactivate rubella virus: ether, acetone, chloroform, deoxycholate, formalin, β-propiolactone, ethylene oxide, free chlorine, and 70% alcohol.⁴⁴⁸ It is resistant to thimerosal.

Antigenic Composition

Rubella virus infection of tissue culture cells results in the production of infectious virus that can be neutralized by specific antiserum. Specific viral antibodies can be identified by hemagglutination inhibition (HI),

complement fixation (CF), precipitation in gel, platelet aggregation, passive hemagglutination, single radial hemolysis, latex agglutination, enzyme-linked immunosorbent assay (ELISA), and immunofluorescence.* Neutralization and HI identify antibodies that inhibit specific biologic functions of the virus, whereas the other assays identify only the formation of antigen-antibody complexes. The E1 glycoprotein is the predominant erythrocyte-binding and neutralization site of the virus.^{586,617} Weak neuraminidase activity also has been associated with purified rubella virus.²⁵

In 1967, Stewart and associates⁵⁵³ reported that tissue culture-grown rubella virus produced hemagglutination of erythrocytes from chickens that were younger than 1 day old and from one goose and one lamb, but no hemagglutination was observed with adult chicken, guinea pig, and other red cell preparations commonly used. Subsequently, techniques involving careful control of test system diluents revealed that red cells from many different animals were agglutinated by rubella virus.^{352,510} Viral hemagglutinin is stable at -20°C (-4°F) for months and at 4°C (39.2°F) for several weeks, but it is destroyed rapidly by heat.^{206,246}

Sever and colleagues³²⁴ first demonstrated that supernatant fluid from primary African green monkey kidney (AGMK) and rabbit kidney epithelial cell (RK-13) tissue cultures contained useful complement-fixing antigens. Two distinct rubella complement-fixing antigens exist.⁵¹² One of the antigens is similar in size and weight to the hemagglutinin and infectious virus; the other soluble antigen is smaller, with a buoyant density of 1.08 g/mL. The soluble antigen is noninfectious and does not contain nucleic acid.⁴⁴⁸ Rubella complement-fixing antigens retain their antigenicity after either treatment.

Two major small-particle antigens have been identified in the medium of tissue culture-infected cells by immunodiffusion.^{341,345,513} The two soluble antigens are structural components of the virion, and natural infection with rubella virus results in the formation of serum-precipitating antibodies. The antigens have been designated *theta* and *iota*. Their importance lies in the fact that antibody to the *iota* antigen rarely is observed in the serum of recipients of some rubella vaccines; therefore, they may be of value in studying vaccine-induced immunity.^{68,342}

The E1 glycoprotein is the dominant surface molecule of rubella virus.⁹⁷ It is the main target of the humoral antibody response for detection and elimination of the virus. HI and neutralization sites have been localized to a small segment of the E1 glycoprotein (i.e., E1₂₄₅ to E1₂₈₅). A study identified the myelin oligodendrocyte glycoprotein (MOG) as the host cell receptor for the rubella virus that interacts with the E1 glycoprotein. Blocking this MOG attachment site of rubella virus may be a way to prevent rubella virus infection of cells.¹¹⁹

Molecular analysis of rubella virus epidemiology from 1961 to 1997 in North America, Europe, and Asia found no major antigenic variations.¹⁹⁹ Further phylogenetic analysis of a collection of 103 E1 gene sequences from rubella viruses isolated from 17 countries from 1961 to 2000 found the existence of at least two genotypes.⁶⁴⁷ Previous work identified rubella genotype 1 isolates predominantly in Europe, Japan, and the Western Hemisphere, whereas genotype 2 isolates were limited to Asia and Europe. In 2013, the WHO adopted a new nomenclature to categorize all of the genetic variants of rubella found.⁶⁴¹

Tissue Culture Growth

Rubella virus grows in many different tissue cultures, including cell strains, cell lines, and primary cells.^{137,370,371,435,448,634} Cell sources include mature and embryonic tissue from humans and other primates, rabbits, swine, dogs, birds, hamsters, and cattle. In tissue culture, growth of rubella virus can be identified by its cytopathic effect or its ability to interfere with the growth of another tissue culture-susceptible virus.

The method used most commonly for primary isolation of rubella virus from clinical material is the interference technique with primary AGMK cells.⁴³⁴ In this system, nonadapted rubella virus grows readily but does not produce a cytopathic effect. Infection is demonstrated in AGMK tissue culture by the failure of a typical enterovirus cytopathic effect to occur after the culture is challenged with echovirus 11 or another suitable enterovirus. A common alternative to the

*References 33, 42, 95, 99, 100, 166, 167, 180, 196, 270, 341, 342, 367, 439, 448, 496, 495, 597, 648.

AGMK–echovirus 11 interference system for primary isolation of rubella virus is use of the RK-13 cell line, in which infection can be identified by a cytopathic effect. For laboratory study and determination of neutralizing antibody, many different cell lines (e.g., RK-13, baby hamster kidney cell [BHK]-21, rhesus monkey kidney epithelial cells [LLC-MK2]) can be used. The highest titers of rubella virus are produced in the BHK-21 and Vero cell lines.

Kinetic studies in tissue culture indicate that virus adsorption is complete within 90 minutes and that the eclipse period lasts approximately 12 hours. The first new virus observed is cell associated; it is followed in 2 to 4 hours by extracellular virus. In primary cell culture, titers of cell-associated and free virus reach 10^3 tissue culture infectious dose (TCID)₅₀/mL by the fourth day; peak titers are not attained until approximately the 17th day. In all cell systems, chronic infection occurs but is limited in some cultures by the cytopathic effect. Rubella virus induces the formation of plaques in several cell lines.

Animal Susceptibility

Although natural infection occurs only in humans, several other primates have been infected experimentally.^{370,435,448} In addition to primates, rabbits, hamsters, ferrets, guinea pigs, and suckling mice have been infected with rubella virus.

EPIDEMIOLOGY

In contrast to measles and other diseases with apparent dramatic cycles, knowledge of rubella epidemiology has been acquired primarily during the past 85 years. Major events during this period that stimulated interest in its epidemiology were the observation of teratogenicity in 1941,²³³ the isolation of the virus in the early 1960s,^{434,622} and the pandemic of 1964. Because rubella was not a reportable disease in the United States until 1966, considerable gaps exist in the available information. We are in a new epidemiologic era because of the widespread use of rubella vaccine. Predicting the incidence of rubella must take into account the extent and method of vaccine use in the population under surveillance.

Incidence and Prevalence

Epidemic Behavior

The epidemic pattern of rubella in selected areas of the United States in the prevaccine and early vaccine eras is shown in Fig. 174.1. The rubella epidemic cycle was usually described as one of 6- to 9-year intervals, with each cycle consisting of a buildup and fall in incidence during the course of a 3- to 4-year period.^{285,286} However, a close look at Fig. 174.1 suggests that the basic pattern in the prevaccine era was a 3.6-year cycle. Of the 11 peaks from 1928 to 1968, all but two occurred in a 2- to 4-year span, with a median of 3 years. Beyond the 3-year

cycle is the better-known 6- to 9-year cycle of major disease. Pandemics occurred in the periods of 1941 to 1944 and 1963 to 1965.

The US rubella pandemic of 1964 to 1965, which initially began in Europe in 1963, exemplifies the extent of morbidity that rubella has the potential to cause.⁴⁴⁹ At that time, there were an estimated 12.5 million cases of rubella, including more than 2000 cases of encephalitis, 11,250 fetal deaths, 20,000 cases of congenital rubella syndrome (CRS), 3580 deaf-blind children, and 1800 children with mental retardation.⁶³⁹

Since the introduction and widespread use of rubella vaccine in the United States, epidemic rubella has occurred only once on a national scale (Fig. 174.2).^{82,81,467} In 1991, 1401 cases of rubella and 47 cases of CRS were reported.⁸⁴ During the next decade, 76 cases of rubella (yearly median of 8 cases) and six cases of CRS were reported (see Fig. 174.2). Rubella virus is no longer circulating in the United States, and the cases that have occurred in recent years have been importations.^{83,468} On October 29, 2004, an expert review panel from the Centers for Disease Control and Prevention (CDC) declared that the rubella virus had not been an endemic threat since 2001 in the United States.

Another remarkable achievement has been rubella eradication from the Americas, especially because as many as 135,947 cases were confirmed in the Americas in 1998.^{69,85} In 2003, the Pan American Health Organization strengthened efforts to eliminate rubella and CRS from the Americas by 2010. They accomplished this goal with high immunization coverage through programs targeting more than 450 million people, including mass vaccination of adolescents and adults, and increased surveillance for rubella and CRS that was integrated into existing measles surveillance programs. As a result of these comprehensive efforts, the last endemic rubella case documented in the Americas was reported in Argentina in February 2009, and the region was declared free of endemic rubella transmission in April 2015.^{69,86,85,228,431}

In countries in which effective universal childhood immunization had not been achieved, epidemics continue to occur. Although the number of rubella cases on a global scale continues to decrease, rubella remains a problem in many areas of the world. Based on data from 2014 collected by the WHO, 33,068 rubella cases from 161 countries were reported, which is a 95% decrease from the 670,894 cases reported in 2000 from 102 countries.^{228,558,638} There was also an increase in the number of countries reporting rubella cases and CRS cases during this time.

From 2002 to 2014, there were decreased numbers of cases in the Americas, European, and Eastern Mediterranean regions. In the Americas region, there was a decrease from 39,228 cases in 2000 to no new cases since 2009, a 1000-fold decrease in the European region (i.e., 621,039 cases in 41 countries in 2000 to 640 cases in 37 countries in 2014), and a 6% decrease in the Eastern Mediterranean region (i.e., 3122 cases to 2945 cases).⁴⁷⁵

FIG. 174.1 Rubella incidence for 1928–83 in 10 selected US areas: Maine, Rhode Island, Connecticut, New York City, Ohio, Illinois, Wisconsin, Maryland, Washington, and Massachusetts. Total	100.0	24.3	100.0	0.2	–99.2

^aReported cases per 100,000 people. Patients with unknown age are excluded.
^bAverage annual figures during a 3-year period.
^cRepresents prevaccine years. National age data were not available before 1975 and were not reported consistently (i.e., >75% of cases) until 1980.
^dTotal United States data (i.e., 1986 population projections) are used for 1985–87; because the overall number of reported rubella cases currently is small, fluctuations (e.g., epidemic in New York City in 1985) in only these three reporting areas skewed the data for this period.
^eBased on actual rates.
From Centers for Disease Control and Prevention: Rubella and congenital rubella syndrome: United States 1985–1988. *MMWR Morb Mortal Wkly Rep*. 1989;38:173–8.

In contrast, reported rubella cases increased in the Western Pacific, Southeast Asian, and African regions during this period. There was a twofold increase (i.e., 5475 to 12,814 cases) in the Western Pacific region, an eightfold increase (i.e., 1165 to 9263 cases) in the Southeast Asian region, and an eightfold increase (i.e., 865 to 7402 cases) in the African region.^{228,472}

Epidemic rubella was documented in the former Czechoslovakia in 1972; in Greece in 1993 and 1999; in Australia in 1969 to 1970, 1975 to 1976, 1993 to 1996, and 2003; in Israel in 1972, 1979, and 1983; in Japan in 1975 to 1977, and 2012 to 2013; in Vietnam in 2010 to 2011, and 1982 to 1998; in Brazil in 1981 and 1997 to 2001; in Argentina in 2008; in the United Kingdom in 1971 to 1973, 1978, and 1983; and recently in some European countries.^{*} A notable outbreak occurred in the Netherlands from 2004 to 2005, which primarily affected individuals unvaccinated due to religious beliefs. Three hundred eighty-seven cases of rubella were reported in the Netherlands and then spread to Canada, where an additional 309 cases were reported. An unfortunate consequence of vaccine refusal in these populations included 14 reported infants with congenital rubella infection and two fetal deaths.²⁴³ Other outbreaks were also reported in Georgia in 2004 to 2005, northeastern Italy in

^{*}References 175, 186, 191, 211, 222, 244, 254, 284, 301, 309, 336, 337, 378, 432, 475, 500, 541, 561, 565, 566, 581, 599.

2008, Austria in 2008 to 2009, and Bosnia and Herzegovina in 2009, which were thought to be the result of vaccination failure rates during the war period in the early 1990s.^{138,158,292,308,415,509}

The incidence of rubella varies with the epidemic cycle, the number of susceptible people in a population group, and the level of intrapersonal contact within the group. In closed populations such as military training centers and institutions for the mentally handicapped, the attack rate after the disease is introduced approaches 100% among susceptible individuals.^{288,289,347} Introduction of disease in the family also affects virtually all susceptible people.^{208,209} In community epidemics, estimated attack rates for susceptible people are 50% to 90%.

Age Groups

The age distribution of reported rubella cases and estimated incidence rates in Illinois, Massachusetts, and New York City for 1966 through 1968 and the entire United States for 1985 through 1987⁸¹ are presented in Table 174.1. In the period immediately before the vaccine was introduced (1966–68), the attack rate was highest in the 5- to 9-year-old age group, and the incidence was high among preschool-aged children. The overall reduction in the rate of rubella from the prevaccine era to 1987 was 99.2%. However, 50.2% of the cases reported between 1985 and 1988 were people older than 19 years; in the prevaccine period (1966–68), the percentage for this age group was 10.2%. In 1999, 75%

FIG. 174.3 Percentage of children with rubella hemagglutination inhibition antibody titers of 1:8 or greater in a St. Louis, Missouri, study in 1969. (From Cherry JD. Rubella: past, present, and future. *Volta Rev*. 1974;76:461–5.)

of the reported cases were people older than 19 years.⁴⁶⁹ From 1980 to 2002, outbreaks of rubella occurred in prisons,⁷⁷ in colleges and universities,⁷⁵ in hospitals,^{74,456,555} at work sites,^{76,223,469} in communities with high concentrations of foreign-born people,⁴⁶⁹ and among the Amish in six areas of the United States.⁸⁰

Because rubella was not a reportable disease in the United States until 1966, few age-specific incidence or prevalence data on epidemic disease are available. In Table 174.2, age-specific attack rates are presented for two communities during epidemic rubella in 1964.¹¹⁷ The attack rate curves during the 1964 rubella epidemic are similar to the curve for the prevaccine nonepidemic period from 1966 to 1968 (see Table 174.1). The overall attack rate during the 1964 epidemic in the two communities was 23%. Children younger than 15 years of age accounted for 86% of the cases. In 1999, 272 cases of rubella were reported in the United States, and of the 269 patients with known ages, children younger than 15 years of age accounted for only 14%.⁴⁶⁹

Data on antibody prevalence by age group in the prevaccine era in the St. Louis, Missouri, area are presented in Fig. 174.3.¹⁰³ The rubella HI antibody prevalence went from less than 10% among children younger than 3 years of age to almost 80% among preadolescents. Surveys of adolescents and young women of childbearing age conducted before 1969 typically indicated an immunity rate (i.e., HI antibody titer $\geq 1:8$) of 75% to 85%.¹¹⁸

Immunity to rubella as indicated by the curve in Fig. 174.3 is affected by epidemic periods. With epidemic disease, the curve probably maintains the same slope, but it moves to the left; the prevalence of antibody in each age group of children increases significantly (10–30%). However, studies in the prevaccine era on sera from young adults indicate that the percentage of susceptible people in this age group is affected only slightly by epidemic disease.^{118,186,522,527,634} In a survey of sera from 600 pregnant women in 1962, Sever and associates⁵²⁷ found that 17.5% had no detectable antibody. In a similar study in 1966 in which the mean age was slightly less (23.6 vs. 25.6 years), 7.8% had no detectable antibody. Other surveys of rubella antibody in the sera of young adults acquired after the 1964 pandemic indicate a susceptibility rate in the 15% to 20% range, similar to pre-1964 data.^{118,520,527}

Effect of Vaccination

Rubella vaccine was licensed for use in the United States and many other countries in 1969, and it has been used extensively for more than 50 years.^{90,118,457,470,469,520,527,616} However, before the 1990s, rubella-containing vaccines were primarily limited to developed countries.⁴⁷² Significant progress has been made in increasing the number of countries that vaccinate routinely against rubella since 1996. As of 2014, the WHO estimated that 140 of 194 member states used rubella-containing vaccines in their national immunization schedules.^{228,639}

As a result of successful rubella vaccination efforts, endemic rubella elimination has been achieved in the United States since 2001 and in many other developed countries. The success of elimination of rubella from the region of the Americas, with the last reported case in 2009, provided hope that rubella could be eradicated globally. However, the risk for importation of rubella into the United States remains high because rubella continues to be endemic in many parts of the world.³⁹ It is imperative to maintain rubella vaccination coverage greater than 90% in the United States. It was estimated by the National Immunization Survey (NIS) in the United States that vaccination coverage for children 19 to 35 months of age was greater than 90% during 2010 to 2014, and data from school surveys of kindergarten children estimated median vaccine coverage of 94% for two doses of measles-mumps-rubella (MMR) vaccine.^{91,92,471}

It has been estimated by mathematical models that when vaccine coverage is low through suboptimal childhood-only immunization efforts, viral circulation may be decreased such that children normally infected during childhood may remain susceptible until adolescence and adulthood. The paradoxical effect of sustained low levels of rubella immunization in childhood can increase the risk of CRS more than without vaccine introduction. The WHO recommends rubella immunization coverage of 80% or greater, with at least one dose of rubella vaccine, because the effectiveness of one dose of vaccine is 95% or greater.⁶³⁹

The immunization effort in the United States initially focused on children.^{146,324,328} A secondary goal was to immunize seronegative postpubertal girls and women of childbearing age, but little effort was extended in this area until 1978. The overall effect of the immunization effort in the United States on the young adult population is difficult to interpret. As shown in Table 174.1 and by subsequent data, the reported number of cases and the incidence of rubella decreased significantly

from the prevaccine period until the present.^{86,82,84,431,469,616} A marked reduction in the number of reported cases of congenital rubella also has occurred since 1969 (see Fig. 174.2). However, the actual number of cases and the incidence of rubella among adolescents and young adults did not decrease until 1981, and 58.2% of all patients from 1985 through 1987 were 15 years of age (see Table 174.1). The marked upswing in the number of congenital rubella cases in 1990 and 1991 was also alarming.^{75,469} Antibody survey data reported between 1981 and 1993 indicate that 5% to 25% of the adolescent and young adult populations in the United States were susceptible to rubella.*

In four studies in which the prevalence of rubella antibody was analyzed by the vaccination status of the participants, differences were significant.^{339,389,421,478} Between 87% and 96% of vaccinated people had rubella antibody, whereas only 70% to 80% of nonvaccinated people had antibody.

US serosurvey data for the period 1988 to 1994 found the following seropositive rates by age group: 6 to 11 years, 91.8%; 12 to 19 years, 82.6%; 20 to 29 years, 84.6%; 30 to 39 years, 88.7%; 40 to 49 years, 92.5%; 50 to 59 years, 93.7%; and 60 years or older, 95.7%.¹⁶⁴ In this survey, people born from 1970 to 1974 were found to have the lowest rate of seropositivity (78%). For the period 1999 to 2004, the overall US seropositivity level was 91.3%. Selected age-related rates for children 6 to 11 years of age and adolescents 12 to 19 years of age were 96.2% and 93.7%, respectively.²⁹⁴ The seropositivity rate was 91.5% among women and 88.0% among men. Among air force recruits in Texas from 2013 to 2014, the rubella seropositivity rate was 82.1%.³⁵¹

In contrast to the immunization program in the United States, which focused on children and elimination of epidemic rubella, immunization efforts in the United Kingdom and many other countries initially were aimed at girls 11 to 14 years of age, with selective immunization of women of childbearing age. This approach would not be expected to disrupt the epidemic pattern of rubella but only to decrease disease in young adult women. Serologic surveys in the United Kingdom indicated a significant reduction in the number of seronegative people in the target population.^{112,247,389,390,392,484,580} In one study in which 10,000 serum samples were analyzed, 93% to 96% of girls born after 1956 (who would have been offered rubella vaccine in school) were found to have antibody, whereas only 80% to 89% of those born before 1954 were found to have antibody.¹¹²

Despite the high level of antibody prevalence among women of childbearing age, rubella infection in pregnancy and congenital rubella continued to be a major problem in the United Kingdom.^{392,580} From 1971 to 1982, 625 cases of congenital rubella were reported, and from 1974 to 1981, 3273 women had their pregnancies terminated because they were infected with rubella or had been in contact with a person with rubella in England and Wales.⁵⁸⁰

In Finland, where initial immunization in 1975 involved 11- to 13-year-old girls and after 1982 involved a two-dose program for all children, the susceptibility rate in 1992 for 16- to 19-year-old girls was 3% to 5%, whereas it was 30% for boys.⁵⁹³

In Sweden, the initial immunization program, which began in 1973, targeted school girls, susceptible women after pregnancy, and women at special risk. Their second program, which began in 1982, was a universal two-dose schedule at 18 months and 12 years.⁵² The rate of susceptibility among pregnant women in Sweden decreased from 12% in 1975 to below 2% in 1994.

Serosurveys from around the world have found various rates of seropositivity for adults.^{115,143,155,302,587} In Jordan, 90.9% of women of childbearing age were immune, but only 83% of females 15 to 19 years of age were immune.³⁰² In Catalonia, Spain, 98.1% of adults had antibody to rubella.¹⁵⁵ In Israel, approximately 95% of women of childbearing age were immune to rubella, whereas only approximately 85% of men of similar age were immune.¹¹⁵ In this serosurvey, as many as 40% of male adolescents were rubella nonimmune, but only approximately 5% of similarly aged girls were nonimmune.

In Taiwan, the prevalence of rubella antibody among women varied markedly by birth cohort.⁵⁸⁷ Rubella antibody was undetectable in 19.9% to 29.2%, 7.1% to 7.3%, and 8.3% to 10.4% of cohorts born before

1971, between 1971 and 1976, and after 1976, respectively.³⁵⁴ In Argentina in 2002, 91.2% of women of childbearing age had antibody to rubella.¹⁴³ A survey of 17 European countries and Australia from 1996 to 2003 showed seronegativity among women of children-bearing age without protective immunity to rubella ranging from 1.4% to 13.4%, lowest among the population of the Czech Republic and highest in Belgium.⁴¹⁰

Data from pregnant women in Canada from 2002 to 2005 found that 8.8% of those tested were seronegative for rubella and that younger women were more likely to be seronegative.³¹⁰ A study from 2000 looking at women of childbearing age in Morocco found that 16.6% were seronegative for rubella immunoglobulin G (IgG) antibodies.⁶⁵ Sero-prevalence data from Nepal in 2008 demonstrated that 90.8% of women of childbearing age were seropositive for rubella.⁵⁹⁵

Congenital Rubella

Rubella infection during pregnancy, especially during the first 12 weeks of gestation, can lead to miscarriage, intrauterine fetal death, and a variety of birth defects associated with CRS.^{162,530} As a result of rubella vaccine implementation, the number of cases of congenital rubella has decreased dramatically, especially in developed countries (see Fig. 174.2). As of 2015, rubella-containing vaccines were introduced into the vaccination schedules of 140 WHO member countries.²²⁸ However, in many regions of the world, immunization against rubella is not standard practice, and congenital rubella infection and its devastating consequences remain an ongoing problem. In many developing countries that have still not implemented mass rubella immunization campaigns, CRS annual rates are estimated to be similar to those in 1996. CRS at that time was estimated at 110,000 cases annually (range, 14,000–308,000 cases), with an estimated 22,000 cases in Africa; 46,000 cases in Southeast Asia; and 12,634 cases in the Western Pacific Regions.^{558,639}

In 2011, the WHO Global Measles and Rubella Laboratory Network (LabNet), which includes 690 laboratories in 183 countries, had a goal of improving reporting and monitoring vaccination and viral transmission.⁶⁴⁰ As of 2014, 161 countries reported rubella cases and 114 countries reported CRS cases. Unfortunately, accurate data continue to be severely limited by underreporting. In 2014, only 141 cases of CRS were reported, and 86 of them were localized to the Southeast Asia region.²²⁸ The global estimate for 2010 was 103,000 CRS cases.⁵⁵⁸ Sero-prevalence data and models also attest to the issue of underreporting. These models predicted approximately 46,621 infants annually with CRS in Southeast Asia, although only 86 cases were reported in 2014 in this region.^{228,638,640}

Because congenital rubella was not a reportable disease in the United States until 1966, good data on incidence and prevalence during epidemics of rubella are not available. In the 1964 to 1965 rubella epidemic in the United States, 20,000 cases of congenital rubella occurred, 5000 therapeutic abortions were performed, fetal wastage in excess of 6250 was reported, and more than 2100 neonatal deaths occurred.¹¹⁸ The estimated risk of acquiring congenital rubella after maternal infection vary considerably across studies. Studies performed before 1964, which included nonepidemic periods, tended to underestimate the risk, whereas early retrospective studies after epidemics resulted in high incidence values.¹⁸⁷

The individual risk of acquiring congenital rubella depends on the month of pregnancy in which maternal infection occurs. Sallomi⁴⁹⁴ analyzed eight published studies that met his rigid criteria and found the following rates of anomalies by gestational age when maternal infection occurred: weeks 1 to 4, 61%; weeks 5 to 8, 26%; and weeks 9 to 12, 8%. In pregnancies complicated by rubella in weeks 1 to 8, only 36% ended in normal live births, 39% ended in abortion or stillbirth, and 25% produced gross fetal anomalies. Peckham⁴³⁸ found that 85% of infants born to mothers infected during the first 8 weeks of pregnancy had detectable defects during the first 4 years of life. Infection at other times during pregnancy revealed the following rates of detectable defects: 9 to 12 weeks, 52%; 13 to 20 weeks, 16%; and after 20 weeks, no defect. Other studies indicate a risk for malformation of 3% and a risk for abortion and stillbirth of 4% when intervals from conception to acquisition of rubella are greater than 12 weeks.¹¹⁴

Infection with rubella virus confers lifelong immunity against clinical illness, but asymptomatic reinfection does occur. Asymptomatic reinfection is observed frequently in pregnant women, but it usually has not

*References 139, 157, 196, 312, 339, 421, 422, 478, 515, 551, 556, 608.

been considered a risk to the fetus. However, in rare instances, reinfection has resulted in severely damaged infants.^{2,24,27,63,141,479,618}

Transmission

Rubella infection likely spreads by the respiratory route. Although definitive evidence supporting this assumption is not available, data from volunteer projects and studies of natural disease strongly support this view.^{232,268,506} Infected people regularly shed large concentrations of virus in the nose and throat, and droplets of secretions are released into the environment, which allows respiratory-to-respiratory transmission. It is also possible that the initial hosts contaminate their own hands and then transmit the infectious agent to environmental surfaces or directly to contacts. In this circumstance, new hosts can acquire infection through the fomite-hand-respiratory or hand-hand-respiratory route.

In experimental transmission studies, Green and colleagues²³² found that efficient transmission of infection to susceptible people required prolonged, repeated contact; after a brief, single contact, only one of five children acquired disease, whereas all but one of 17 patients with prolonged, repeated contact were infected. Although the period of communicability has never been determined accurately, almost 100 years ago, the period of infectivity was observed to precede the eruptive phase of illness.²³⁴ Volunteer studies indicate that virus is present in nasopharyngeal secretions from 7 days before to 14 days after the onset of rash.^{232,268} Maximal shedding and presumably maximal transmissibility occur for an 11-day period of 5 days before to 6 days after the appearance of rash. Infants with congenital rubella shed virus from the nose and throat for many months and have been responsible for the spread of virus to susceptible contacts.^{287,504}

Seasonal Patterns

Rubella is a disease of winter and spring, with the largest number of cases in the United States occurring in March, April, and May.^{118,117} This seasonal pattern occurs in years with a high or a low incidence of rubella. Presumably, some transmission and sporadic illness occur throughout the year in large urban areas.

Geographic Distribution

Rubella has been recognized in many countries throughout the world. In recent years, more information about circulating wild-type rubella viruses has been uncovered largely because of global virologic surveillance efforts for measles, which also incorporates surveillance for rubella. The WHO Global Measles and Rubella Network, which was developed in 2000, serves more than 183 countries and includes more than 690 laboratories, which helps confirm suspected cases of rubella and monitors rubella transmission patterns.^{176,487} Nine of the 13 viral genotypes were identified during surveillance efforts from 2005 to 2010. Viruses 1E, 1G, 1J, and 2B have the widest geographic distribution and are the most frequently identified.⁶⁴¹ 1E Rubella viruses were found in the Middle East, Europe, Southeast Asia, Africa, and Western Pacific countries. This genotype is also the dominant one found in China. The 1G genotype viruses were found in Europe and Africa. The 2B genotype viruses were found in the Middle East, Europe, Southeast Asia, and South and Central America, Africa, and Western Pacific countries.¹

In remote islands, rubella may not be endemic, and large segments of the population may be susceptible.^{56,273} In these locales, the introduction of rubella results in epidemic infection that involves approximately 90% of the susceptible population. In populated areas of the world in the prevaccine era, rubella was endemic and epidemic, and between 80% and 90% of the adult population had serum rubella antibody.¹¹⁴ In the prevaccine era in several well-populated large islands that were not remote (i.e., Jamaica, Taiwan, Barbados, Trinidad, Hawaii, and Japan), a smaller percentage of the total population had antibody, and rubella was not endemic.^{114,173,209,229}

Other Factors

Sex

The incidence of clinical rubella is similar among boys and girls.^{118,117} Among adults, more cases of rubella are reported for women than men.¹¹⁸ This finding possibly is the result of interest and concern related

to congenital rubella rather than a true difference on the basis of sex. In rubella vaccine trials, girls have had geometric mean convalescent-phase antibody titers higher than those of boys.^{387,543}

Mitchell and associates³⁹⁶ studied the IgG, IgM, and IgA antibody responses in men and women to rubella virus structural proteins (i.e., E1, E2, and C). IgA E2 antibodies did not develop in men, but they did in women. Men had lower IgG antibody levels to E2, an earlier onset of E1-specific IgG and IgM antibodies, and a greater proportion of total antibody against E1 than women did. In another study, Mitchell³⁹³ reported that men had a more rapid cell-mediated immune response to whole, inactivated rubella virus and a panel of rubella virus peptides after reimmunization than women did.

Genetics

Hattis and associates²⁶⁴ showed that individuals differ in their ability to transmit rubella. During a rubella epidemic, they identified a small number of people who had high potential for transmitting virus to susceptible people (i.e., spreaders). Most people demonstrated only minimal virus transmission (i.e., nonspreaders). Honeyman and colleagues^{279,282} in 1975 suggested that the ability to spread rubella virus is favored by the cell surface human leukocyte antigen 1 (HLA-1) or the combination of HLA-1 and HLA-8. In a rubella vaccine trial in 1974, Spencer and associates⁵⁴³ found that 44% of people with high rubella HI antibody titer ($\geq 1:512$) responses had HLA-W16. In this study, a high convalescent-phase geometric mean antibody titer was found in people with the AB blood type.

Ovsyannikova and associates⁴²⁶ studied HLA haplotypes in the genetic control of the immune response to the MMR vaccine. They found that DRB1*04-DQB1*03-DPB1*03 was associated with high lymphoproliferative responses to rubella vaccine virus. They found that specific class II HLA haplotypes (i.e., DRB1*04-DQB1*03-DPB1*03 and DRB1*13/14-DQB1*06-DPB1*03) were associated with higher lymphoproliferative responses to rubella virus vaccine and that the haplotype DRB1*07-DQB1*02-DPB1*11 was associated with lower lymphoproliferative responses.⁴²⁷

Kennedy and associates³¹³ found that homozygosity within HLA DPB1 locus was associated with increased levels of rubella-specific IgG antibody. Haralambieva and colleagues²⁵⁵ found associations between polymorphisms within the 2'-5'-oligoadenylate synthetase gene (OAS) cluster and rubella virus-specific cytokine secretion (i.e., IL-2, IL-10, and IL-6) and antibody levels.

PATHOLOGY AND PATHOGENESIS

Viral Infection

The sequence of events in uncomplicated, postnatally acquired rubella is presented in Table 174.3. Although much is known about rubella infection in humans, considerable gaps regarding specific events exist.^{232,266-268,506} Estimates for the timing of events in rubella infection (see Table 174.3) have come from volunteer inoculation studies. In many instances, artificial inoculation has resulted in a reduction in the length of the incubation period of clinical disease. This finding suggests that the size of inoculum is important in the initial generation of human infection. It also helps explain the wide boundaries of the incubation period reported in many clinical studies.^{234,384,499}

The primary site of infection is the respiratory epithelium of the nasopharynx. Initial infection of the respiratory epithelium apparently is minor; a more important event is early spread of virus to the regional lymphatics. In volunteers given 100 TCID₅₀ of rubella virus intranasally, viral multiplication at the respiratory site was found on the third day.⁵⁰⁶ After viremia develops, extensive nasopharyngeal infection occurs. In people who have received attenuated or unattenuated virus by the subcutaneous route, nasopharyngeal shedding in various concentrations always occurs.^{105,106,232,506} Concentrations of virus typically are greater in specimens collected from the nose than in those from the throat.

Viremia peaks just before the onset of exanthem and disappears shortly thereafter. In contrast, virus continues to be present consistently in the nasopharynx for a 6-day period after the onset of rash and occasionally for an additional week thereafter.²³² In addition to the blood and nasopharynx, other sites from which rubella virus has been

TABLE 174.3 Sequence of Rubella Viral Infection in Uncomplicated Primary Disease

Day	Event
0	Rubella virus from the respiratory secretions of an infected person comes in contact with the epithelial surface of the nasopharynx of a susceptible person. Localized infection in the respiratory epithelium is established, and virus spreads through lymphatics and possibly spreads by transient viremia to regional lymph nodes
1–22	Viral replication in localized areas of the nasopharynx and regional lymph nodes
3–8	First evidence of nasopharyngeal viral shedding
6–20	Viremia (i.e., virus free in serum and associated with leukocytes)
8–14	Establishment of infection in the skin and other viremic sites, including generalized nasopharyngeal involvement
10–17	Maximal viremia and viruria
10–24	Maximal nasopharyngeal viral shedding
17–19	Viremia decreases and then ceases. Viral content at viremic sites rapidly diminishes

Data from references 232, 266–268, 506.

recovered are the lymph nodes,²⁰⁵ urine,⁵⁰⁶ cerebrospinal fluid,⁵⁴⁷ conjunctival sac,²⁶⁷ breast milk,⁶⁰ synovial fluid,²⁷¹ and lungs.⁵³¹ In patients with rubella, the virus was recovered from the skin at sites with rash or without rash.^{266,267}

Immunologic Events

Antibody

After having natural or vaccine rubella viral infection, patients regularly have an antibody response. Serum antibodies to different rubella viral antigens can be measured by HI, CF, neutralization, immunofluorescence, precipitation, radioimmunoassay, ELISA, single radial hemolysis, passive hemagglutination, latex agglutination, and platelet aggregation.*

In natural postnatal rubella infection, HI and neutralizing antibodies appear 14 to 18 days after exposure, at the time of the rash. HI antibody titers usually peak approximately 2 weeks after the onset of clinical illness, stay at a high level for several weeks, decrease about fourfold during the next year, and then generally persist for life. Immunofluorescence, ELISA, radioimmunoassay, and latex agglutination reveal antibody patterns similar to those determined by HI.²⁷⁰ Antibody detected by passive hemagglutination does not appear until 3 to 4 weeks after the onset of illness, and that detected by single radial hemolysis is delayed until 1 to 2 weeks after onset. In an Amazon Indian tribe, the geometric mean rubella HI antibody titer 12 years after infection, with no intercurrent rubella exposure, was 1:33.⁴³ The pattern of the neutralizing antibody response is similar to the HI antibody response, except that the peak is delayed slightly. Brody and colleagues⁵⁶ found that all but 10% of an island population had rubella neutralizing antibody 22 years after the time of epidemic illness.

CF antibody first appears approximately a week after HI and neutralizing antibody, peaks approximately 1 month after illness, and usually does not persist as long as HI or neutralizing antibody. Occasionally, the CF antibody response is delayed and appears 1 month after the exanthem, with peak titers occurring 2 to 5 months later. Sever and colleagues⁵²⁵ identified CF antibodies in only 44% of people with neutralizing antibody who were studied 10 to 20 years after illness. The use of an antigen prepared by alkaline extraction has increased the sensitivity of CF, but low levels of antibody are best identified by HI, ELISA, or neutralization.^{448,511}

After natural infection occurs, precipitating antibodies develop to the theta and iota antigens.³⁴¹ Antibody to theta antigen appears early, parallels HI antibody, and is persistent. In contrast, the response to iota antigen is delayed, with a slow rise in concentration during a 2- to 3-month period. Five years after infection has occurred, anti-iota antibody cannot be detected.

After immunization has been administered, the antibody response pattern varies according to the type of vaccine used.^{44,342,420,451,452,505,611} With RA 27/3 vaccine, the serum antibody response is similar to that after natural disease, except that the peak HI and neutralizing antibody titers attained usually are lower. Serum antibody responses found after

HPV-77 and Cendehill vaccine viral infection are different from those found after natural infection in that CF and anti-iota antibodies are observed only irregularly and then in minimal concentrations.

Primary rubella virus infection that is naturally acquired or vaccine induced is characterized by the initial appearance of antibody in the IgM and IgG serum components.^{30,41,132,151,241,436,437,548} The IgM-specific response is short lived and not detectable more than 8 weeks after the onset of infection. Occasionally, it has been detected in the serum for extended periods.

IgA nasal HI, ELISA, and neutralizing antibodies occur regularly after natural viral infection. After immunization, the nasal antibody response varies with the type of vaccine and the route of administration.^{6,7,131,135,420,448}

After subcutaneous immunization with HPV-77 vaccine is given, rubella-specific nasal IgA antibody is a rare finding; it occurs in most subjects who receive RA 27/3 vaccine administered intranasally and in approximately one half of those given this vaccine subcutaneously.

Specific Cell-Mediated Responses

Rubella-specific, cell-mediated lymphocyte responses regularly occur after infection with rubella virus.* Using an in vitro lymphocyte-mediated cytotoxicity assay, Steele and associates⁵⁵⁰ found that lymphocytes from people who previously had rubella caused cell destruction in a tissue culture chronically infected with rubella virus. Rubella antigen-specific, cell-mediated immunity also has been demonstrated in lymphocyte cultures by blast transformation, production of migration-inhibition factor, and production of interferon (IFN).^{62,280,403,540,573,603,604} With vaccination, rubella-specific, cell-mediated immunity begins 7 days after immunization, with peak responses at 3 weeks.^{603,604} Honeyman and associates²⁸⁰ observed that the rubella antigen-specific, cell-mediated response commenced 1 week before the humoral immune response occurred in natural and vaccine-induced rubella viral infection. They also found that the cell-mediated response was of greater magnitude and duration after natural disease than after immunization. Rossier and associates⁴⁸⁶ studied cloistered nuns and found that specific cell-mediated immunity to rubella virus persisted until they reached 79 years of age in the probable absence of reinfection.

Morag and colleagues⁴⁰³ demonstrated the specific appearance of cell-mediated immunity in tonsillar lymphoid tissue after natural infection or intranasal immunization with rubella vaccine. This responsiveness was conspicuously low after vaccination was administered by the subcutaneous route. In most instances, cell-mediated responsiveness correlates with the presence of antibody; however, specific rubella lymphocyte transformation has occurred in the absence of antibody.⁵⁴⁰ The magnitude of the rubella-specific, cell-mediated response is suppressed during pregnancy.⁵⁷³ Seventeen T-cell epitopes have been identified with the lymphoproliferation assay.^{97,394} They involve the capsid protein and E2 and E2 glycoproteins.

McCarthy and colleagues³⁶⁹ identified potential determinants of human cellular immunity to rubella virus by using synthetic peptides

*References 15, 42, 129, 152, 179, 216, 226, 248, 270, 277, 342, 349, 367, 381–383, 407, 439, 448, 523, 524, 578, 601, 605, 630, 648.

*References 97, 269, 280, 307, 358, 361, 369, 393–396, 403, 425, 426, 485, 540, 550, 603, 604.

representing well-defined sequences of rubella virus structural proteins. They used two capsid domains (i.e., C₁ to C₂₉ and C₆₄ to C₉₇), a glycoprotein E1 domain (i.e., E1₂₀₂ to E1₂₈₃), and a glycoprotein E2 domain (i.e., E2₃₁ to E2₁₀₅). All but the C₆₄ to C₉₇ subsequences stimulated specific lymphoproliferative responses in peripheral blood mononuclear cells in 25% to 50% of immune subjects. The immunodominant T-proliferative epitope (i.e., C₁₄ to C₂₉) was recognized by only 50% of the peripheral blood mononuclear cells of the study population. Relatively immunodominant T-cell epitopes vary among different people.

Using a lymphocyte proliferation assay, Mitchell and associates³⁹⁵ reported positive cell-mediated immune responses to 16 peptides, including six that contained antibody neutralization domains after revaccination.

Nonspecific Responses

A large number of nonspecific, immunologically related responses can be demonstrated during rubella virus infections. Niwa and Kanoh⁴¹² performed a comprehensive study of these responses in 85 children and adults during an epidemic of rubella. They found decreased numbers of neutrophils, T cells, and total leukocytes initially, which returned to normal values within 1 week. Some patients had slightly elevated levels of serum IgM, and total hemolytic complement was elevated in 12 of 30 patients. Marked increases in C4 and C9 were found, and they also observed a marked insensitivity to dinitrochlorobenzene and purified protein derivatives in many patients.

Atypical lymphocytes, autoantibodies, and reduced blastogenesis as measured by phytohemagglutinin (PHA) stimulation were detected in some patients. Other studies consistently have demonstrated a reduction in the lymphocyte response to PHA.^{59,67,210,297,333,361,373,412} This reduction typically lasts less than 1 month, and infections with attenuated strains of rubella vaccine virus are less immunosuppressive than are infections with unattenuated rubella virus.

Hyypiä and colleagues²⁹⁷ reported that during rubella virus infection, the proportion of suppressor-cytotoxic T cells was increased and the proportion of helper-inducer T cells was decreased. Polyclonal activation of B cells was associated with these findings.²⁹⁸

Zaknun and coworkers⁶⁴⁵ noticed a marked increase in urine neopterin levels in two children with acute rubella. Their levels increased dramatically 4 days before the onset of exanthem.

Fetal Events

Viral Infection

A considerable amount of information about fetal infection became available from extensive studies during the 1964 epidemic of rubella,* and further information was obtained from natural and vaccine viral infections.^{46,153,165,338,445,519,598,642} Despite the number and extent of investigations performed, little is known about transmission of the virus to the fetus in maternal infections during the latter half of pregnancy.

With maternal infection during the first trimester, placental infection regularly occurs and often persists throughout the remainder of the pregnancy. In the therapeutic abortion studies of Alford and associates,¹⁰ fetal infection occurred in approximately 50% of placental infections. However, other studies have revealed almost identical isolation rates from placental and fetal tissue.^{466,572} Persistent infection is the usual outcome of first-trimester fetal infection. Fetal infection usually involves multiple organs, and virus can be isolated at birth regularly from the throat, rectum, and urine.^{287,446}

Little is known about events in second- and third-trimester maternal rubella infection. Most probably, placental infection is a regular occurrence, and transmission of virus to the infant in utero also may occur regularly. Because few infants have defects when they are born after maternal rubella infection in the second and third trimesters, a careful search for rubella infection in these infants by virologic or serologic methods rarely has been conducted. Random studies seem to indicate that rubella virus often infects the fetus after the first trimester and occasionally the infection becomes persistent.^{134,153,257,287,399,606,626} Other studies have failed to show virologic or serologic evidence of infection

in infants in whom maternal rubella occurred in the second and third trimesters.^{107,400,554}

With maternal rubella infection, the cervix also is involved, and fetal infection can occur by the ascending route as well as by primary placental infection.^{107,400,519,554,598} Fetal infection has resulted from maternal disease that occurred before conception.^{185,627,642}

Rubella virus can be recovered regularly after birth from infants with congenital rubella. The percentage of infants with persistent infection decreases during the course of the first year of life; by their first birthdays; between 10% and 20% of children still shed virus in nasopharyngeal secretions.^{124,466} Rawls and colleagues⁴⁶⁶ were unable to isolate virus from the throats of 15 congenitally infected infants after they reached 18 months of age, and Sever and Moni⁶²⁶ and Cooper and Krugman¹²⁴ were unable to demonstrate persistence of nasopharyngeal virus in older children. A 4.5-year-old boy with congenital rubella was found on one occasion to be shedding rubella virus in the throat.⁵³²

Immunologic Findings

Specific antibody. Humoral antibody in a congenitally infected fetus is acquired transplacentally from the mother and is produced actively by the fetus. In a normal maternal-fetal relationship, transport of antibody to the fetus is minimal until the midpoint of the second trimester (16–20 weeks).^{8,9} With first-trimester maternal infection (i.e., transplacentally acquired), rubella antibody titers in serum amount to only approximately 5% of maternal values. The fetal immune system becomes functional during the second trimester,³⁴⁰ and small amounts of specific rubella fetal IgM antibody can be detected. From the midpoint of pregnancy, antibody levels in the developing fetus rise, and at birth, the maternal and infant values are similar. Although the values of total antibody are similar, the composition is different. Maternal antibody at the time of delivery usually is composed entirely of IgG. In contrast, the infant titer consists of fetal IgM, presumably fetal IgG, and occasionally fetal IgA and transplacentally derived maternal IgG.

Long-term rubella antibody patterns in congenitally infected infants after birth are different from those of their mothers or from those of a group of children with acquired disease.^{122,256,315,590} Cooper and colleagues¹²² monitored a group of 223 mothers of children with congenital rubella and noticed that at the end of 5 years, all still had detectable HI antibody and that the geometric mean titer for the group had undergone a fourfold reduction. In contrast, 5-year follow-up of the congenitally infected infants revealed a 16-fold decline in geometric mean titer; eight of 29 infants had serum HI antibody titers less than 1:8 when they were examined at 5 years of age. Other investigators observed similar declines in rubella antibody titers of congenitally infected infants.^{256,315,590}

Another unique aspect of rubella antibody in congenitally infected infants is the persistence of specific IgM. Cradock-Watson and colleagues¹³³ studied 40 infants with congenital rubella and found that IgM antibody persisted for approximately 6 months in most cases and for up to 2 years in a few children. De Mazancourt and colleagues¹⁴⁴ studied the antibody response to rubella virus structural proteins in infants with CRS and found that the immunoprecipitation patterns were different from those in sera from postnatally infected adults. The sera from congenitally infected infants had little or no C-specific antibody, occasionally only antibody to E1 was precipitated or E1 protein was precipitated in relative excess compared with E2 protein, and the relative amount of E2 antibody was greater than antibody to E1.

Specific cell-mediated immunity. Rubella-specific, cell-mediated immune responses have been studied in children with congenital rubella by the following assays: lymphocyte-mediated cytotoxicity, lymphocyte transformation, lymphocyte IFN production, and leukocyte migration-inhibition factor production.^{61,204} By all methods of study, infants with congenital rubella have decreased rubella-specific, cell-mediated responses in contrast to people who had acquired rubella postnatally. Buimovici-Klein and associates⁶¹ found that the degree of suppression correlated with the time of in utero infection; the earlier in pregnancy the maternal infection, the greater is the depression of specific cell-mediated responses. In the study of an infant with late-onset CRS, Verder and associates⁶⁰² observed decreased activity of killer and natural killer cells and alloreactive direct cytotoxic cells. Their data indicated that defective cytotoxic effector

*References 10, 72, 107, 124, 125, 126, 160, 253, 256–260, 287, 293, 398, 399, 401, 400, 446, 466, 504, 507, 554, 627.

cell function was the primary cause for failure to eliminate virus in the illness.

Nonspecific responses. Desmyter and colleagues¹⁴⁹ found that infants with congenital rubella produced normal amounts of IFN after receiving measles immunization. They also found that the clinical response and antibody development in these measles-vaccinated children were similar to those in normal children. Lebon and associates³⁴³ observed that sera collected from rubella-infected fetuses and infants with congenital rubella contained an acid-labile IFN. Michaels³⁸⁵ found that infants with congenital rubella who still were shedding virus in their throat or urine had depressed antibody responses to diphtheria and tetanus toxoids.

White and colleagues⁶²⁵ reported decreased in vitro lymphocyte blast transformation responses to vaccinia and diphtheria toxoid antigens in children with congenital rubella in contrast to normal children. They also found depressed skin reactivity to intradermal *Candida* antigen in the congenital rubella group. Buimovici-Klein and associates⁶¹ observed a marked reduction in lymphocyte transformation after PHA stimulation in their congenital rubella group. The most marked defect was seen in children in whom maternal rubella occurred during the first 8 weeks of pregnancy.

Pukhalsky and associates⁴⁵⁹ reported that rubella immunization resulted in defective lymphocyte response to a mitogen (i.e., PHA). After immunization, serum IFN- α was slightly increased at day 7 and then fell significantly so that it was not measurable at day 30 in several subjects. The IFN- α to interleukin-10 ratio significantly decreased after immunization.

Pathology

Postnatally Acquired Disease

Almost no data on the histologic findings in uncomplicated rubella are available, but occasionally, postmortem tissue has been studied from patients with encephalitis. Giuliani and associates²²⁰ studied lymph nodes from patients with rubella and reported edema, reticulum cell hyperplasia, and loss of the usual follicular morphologic features. Sherman and associates⁵³¹ reported six cases of rubella encephalitis and the autopsy findings in three cases. They specifically searched all organs for inclusion bodies, syncytial giant cells, focal cellular necrosis, and unusual proliferative changes, but none was found. Only mild, nonspecific, follicular hyperplasia in the spleen and lymph nodes was seen. Histologic examination of the brain of a 7-year-old girl who died of encephalitis revealed diffuse swelling, nonspecific degeneration, and a sparse, mononuclear perivascular and meningeal exudate.

A synovial biopsy specimen from a woman with rubella arthritis revealed scattered areas of fibrinopurulent exudate and synovial cell hyperplasia. Inflammatory cell infiltration composed mainly of lymphocytic cells was identified, and vascularity was increased.⁶⁴³

Congenital Infection

In contrast to postnatal rubella, the pathologic process of congenital infection has been studied extensively.* **Table 174.4** summarizes the main pathologic findings of congenital rubella by anatomic location or system. Defects in congenital rubella result from specific cell damage and cellular deficiency. Although specific cellular necrosis is important in certain early lesions such as in the inner ear, the secondary effects of generalized vascular damage are of greater overall importance. The noncytolytic cellular infection characteristic of rubella virus is also important because it results in mitotic arrest and a reduction in the total number of cells in many organs.

CLINICAL MANIFESTATIONS

Postnatal Illness

Although clinical rubella is a distinctive exanthematous disease, its features are not as clearly discernible as those of measles or chickenpox.[†]

The exanthematous illnesses caused by enteroviruses, adenoviruses, and other common respiratory viruses often are clinically similar or identical to those of rubella (see Chapter 58). Because of these other viral illnesses that simulate rubella, descriptions of clinical rubella made before modern virologic diagnostic techniques became available are not always accurate, particularly when rubella in infants and young children is described because exanthems caused by other viruses occur most commonly in these age groups. Despite the availability of a vast amount of clinical material collected during the rubella epidemic of 1964, most clinical knowledge about postnatally acquired rubella was formulated before the current virologic era.

Incubation Period

Although prodromal complaints and lymphadenopathy frequently precede the development of exanthem in rubella, the incubation period in most studies has been calculated as being from the time of exposure to the onset of rash. Almost a century ago, Michael³⁸⁴ reviewed the incubation periods in 59 different reports and identified a variation of 5 days to 4 weeks. However, in most reports, the minimal incubation time was at least 14 days, and the maximum was 17 to 21 days. The mean incubation period from modern reviews is considered to be 18 ± 3 days.

In carefully controlled studies, Green and colleagues²³² found an incubation time of 13 to 15 days to the onset of rash after the intramuscular inoculation of serum from rubella-infected patients and a longer incubation time (16–21 days) in cases acquired by contact with ill patients. In similar volunteer studies in young adults, Schiff and colleagues⁵⁰⁶ reported that the onset of rash occurred 11 to 12 days after the administration of 100 TCID₅₀ of tissue culture–grown rubella virus. The investigators attributed this shorter incubation period to a larger inoculum than that occurring in natural transmission.

Prodromal Period

Symptoms reported before the onset of rash in rubella vary with age. In young children, the first evidence of disease usually is the appearance of rash. Mild coryza and diarrhea sometimes precede the development of exanthem in younger patients. In contrast to the lack of prodrome in children, adolescents and adults usually have symptoms before the onset of rash (J. Cherry, unpublished data, 1963–73).^{184,236} In one study, 94% of college students with rubella had prodromal symptoms. In decreasing order of frequency, the reported symptoms were eye pain, sore throat, headache, swollen glands, fever, aches, chills, anorexia, and nausea.¹⁸⁴ Gross and associates²³⁶ reported prodromal upper respiratory tract complaints, including malaise, cough, sore throat, red eyes, and runny nose, in 65% of an infected adolescent study group.

Prodromal symptoms usually precede the onset of rash by 1 to 5 days. In the studies of Green and associates²³² involving volunteers, the onset of lymphadenopathy typically occurred 5 to 7 days before the onset of rash. In contrast, Schiff and colleagues⁵⁰⁶ observed the appearance of lymphadenopathy only 1 day before the rash appeared; fever occurred 1 to 4 days before the onset of rash, and most of the volunteers also had malaise and sore throat. Pain on lateral and upward eye movement occurs frequently and is sometimes distressing (J. Cherry, unpublished data, 1963–76).¹⁸⁴

Exanthem Period

The rubella exanthem appears first on the face. The rash spreads centrifugally from the head toward the hands and feet. The progression, extent, and duration of the exanthem vary considerably. In a typical case, the rash involves the entire body during the first 24 hours, begins to fade on the face during the second day, and has disappeared from the body by the end of the third day. The characteristic rash is erythematous, maculopapular, and discrete (**Fig. 174.4**). Its appearance on an adolescent's face occasionally is confused initially with an exacerbation of acne. Frequently, the rash is only macular with a scarlatiniform appearance. In some patients, the rash is present for less than a day, although sometimes it persists for 5 days or longer. Particularly in adults, the exanthem frequently is pruritic. This complaint is troublesome because it often leads the patient and the physician to attribute the rash to an allergic cause rather than rubella virus infection.

TABLE 174.4 Pathologic Findings in Congenital Rubella Cases

Anatomic Location or System	Gross and Microscopic Findings	References
Placenta	Perivascular mononuclear cellular infiltration in the deciduas Edema, fibrosis, and necrosis of villi; cytoplasm inclusion bodies observed in swollen Hofbauer cells in villous stroma	423
Generalized growth retardation	Subnormal number of cells in many organs	408
Nervous system	Chronic meningitis with infiltrates of large mononuclear cells, lymphocytes, and plasma cells in the leptomeninges Vascular degeneration, ischemic lesions, and retardation of myelination throughout brain	481, 482, 536, 574
Eye	Lens: cataract, cortical liquefaction, and spherophakia Iris and ciliary body: necrosis of ciliary body, iridocyclitis, iris atrophy, and pigmentation defects Retina: posterior pigmentary disturbances Cornea: usually normal; occasional endothelial degeneration Optic nerve: posterior bowing	48
Ear	Hemorrhage in fetal cochlea resulting in epithelial necrosis Inflammatory cells in stria vascularis Adhesions between the Reissner membrane and tectorial membrane Sacculocochlear degeneration of Scheibe (i.e., stria atrophy, collapse of the Reissner membrane, atrophy of organ of Corti, rolled-up tectorial membranes, and collapse and degeneration of sacculus) observed after birth	200, 201, 614
Cardiovascular system	Common heart defects in order of frequency: patent ductus arteriosus, pulmonary artery stenosis, ventricular septal defect, and atrial septal defect (these rubella-induced lesions are not different from similar non-rubella-induced lesions) Myocarditis with swelling of muscle fibers and loss of striations; necrosis Intimal proliferation of major arteries	5, 169, 193, 321, 322, 617
Pulmonary system	Chronic interstitial pneumonia with large mononuclear cells, lymphocytes, and plasma cells within interstitial spaces and alveoli	322, 444, 536
Liver	Hyalinization and swelling of hepatocytes, hematopoiesis, and multinucleated giant cells	171, 172, 552, 557
Skin	Purpuric lesion: focal areas of erythropoiesis in dermis and upper subcutaneous adipose tissue Chronic reticulated rash: acute and chronic inflammatory cells and histiocytes in dermis Edema in dermal papillae	71, 319
Bone	Thinning of metaphyseal trabeculae and decrease in number of osteoblasts and osteoclasts Many plasma cells in metaphyses and cartilaginous epiphyses and around vessels Occasional giant cells with cytoplasmic inclusions Thinning of cartilage	467, 489, 518, 624
Muscle	Focal abnormalities: very small fibers with darkly staining nuclei and muscle bundles containing empty connective tissue tubes	543
Teeth	Necrosis of enamel-forming epithelial cells	237, 583
Hematologic system	Transient thrombocytopenia with decreased megakaryocytes in bone marrow; increased platelet adhesiveness and platelet agglutinins Lymph nodes consistent with histiocytosis; unorganized cell mass made up of mononuclear cells with dense round nuclei and irregularly shaped cytoplasm	31, 111, 454, 465
Immunologic system	Spleen: fibrosis Loss of normal architecture and absence of germinal centers in spleen and lymph nodes Dysgammaglobulinemia usually with decreased IgG and IgA and elevated IgM levels	111, 250, 453, 476

The exanthem occasionally progresses to confluence with a morbiliform appearance. In these cases, the rash usually is less coppery and pinker than that in measles, and it heals without desquamation or brownish discoloration. The typical picture of erythema infectiosum (i.e., slapped-cheek appearance and reticular rash) has been observed in rubella-infected patients. Balfour and associates²² described eight children with erythema infectiosum from whom rubella virus was recovered concurrently and two additional children with serologic evidence of rubella infection. The preliminary results of volunteer studies with a virus recovered from one of the patients in this study produced a slapped-cheek appearance but a nonreticulated rash in four of five men. One 3-year-old child from whom the investigator recovered rubella virus had typical erythema infectiosum (J. Cherry, unpublished data, 1972). A 14-month-old girl had a roseola-like illness and arthritis.²⁷¹

In the volunteer studies of Schiff and associates,⁵⁰⁶ the pink-red rash was maculopapular. It appeared initially on the face, chest, upper part

of the arms, and shoulders and then spread rapidly over the abdomen, back, and thighs. It developed into an erythematous blush on the face and abdomen. The median duration was 3 days, with extremes of 2 and 5 days. Patients had no pruritus.

Rubella infection without rash is a common occurrence. In some patients, the infection occurs without symptoms; in other people, careful questioning reveals prodromal symptoms, and lymphadenopathy is found on examination. Green and associates²³² reported that approximately 25% of exposed children who became infected had subclinical infection. In an intensive study of 46 susceptible children and adults, all but one person had clinical symptoms with infection⁵²¹; 60% of the group had rash and characteristic posterior auricular or suboccipital lymphadenopathy, and 40% had lymphadenopathy without rash. In another study of rubella in an institution for intellectually challenged children, Horstmann and associates²⁸⁹ observed that only about one half of the children who became infected had a rash. Of nine children without rash, significant posterior auricular lymph node enlargement

FIG. 174.4 Rubella exanthem. The rash is erythematous, maculopapular, and discrete. (From Cherry JD. Newer viral exanthems. *Adv Pediatr*. 1969;16:233–86.)

developed in five. Buescher⁵⁸ reported a subclinical-to-clinical infection ratio in a military recruit population of 6.5:1.

Lymphadenopathy is a major clinical manifestation of rubella. The most characteristic enlargement occurs in the suboccipital and posterior auricular nodes, but generalized involvement also occurs. In the volunteer studies of Schiff and colleagues,⁵⁰⁶ the lymph node enlargement usually lasted 5 to 8 days. In two outbreak studies involving adolescents and young adults, posterior auricular and suboccipital lymphadenopathy occurred in all patients with rash.^{184,236} In contrast to these findings, Landrigan and associates³³⁵ reported that only 47% of children and 58% of adolescents had similar lymph node enlargement during epidemic rubella illness.

The frequent suggestion that the finding of exanthem and suboccipital lymphadenopathy is pathognomonic for rubella is incorrect. In young children, similar involvement is seen frequently with enteroviral and adenoviral infections. In adolescents and young adults, the association more strongly indicates rubella, but infectious mononucleosis, *Mycoplasma pneumoniae* infection, acquired toxoplasmosis, and other possibilities must be considered.

When fever develops in rubella, the temperature usually is elevated only minimally. For children with experimentally induced rubella, Krugman and Ward³²⁹ reported that five of 13 had temperatures of 38°C (100.4°F) or higher. Two children had maximal temperatures of 38.5°C (101.6°F). Schiff and colleagues⁵⁰⁶ found that all nine infected volunteers had fever with a median duration of 5 days. Landrigan and associates³³⁵ found fever in 74% of children and only 47% of adolescents. Gross and coworkers²³⁶ observed fever in only six of 17 adolescents. Children with apparent rubella occasionally have markedly elevated temperatures.

Because few of these cases have undergone virologic study, some doubt remains about whether the illnesses were induced by rubella virus or were caused by other viral agents more commonly associated with marked febrile responses, such as enteroviruses and adenoviruses. We have seen an 8-year-old boy with virologically and serologically confirmed rubella with a temperature of 40°C (104°F) on the day before the appearance of his rash. The 14-month-old girl with arthritis described by Hildebrandt and Maassab²⁷¹ had a temperature as high as 40.5°C (105°F).

In 1898, Forchheimer¹⁸⁸ described what he thought was the enanthem of German measles. He described pinhead-sized macular lesions with a rose-red color on the soft palate and uvula that appeared at approximately the time of the exanthem and lasted less than 24 hours. This exanthem has not been identified in children we have examined; however, petechial lesions on the soft palate and uvula have been seen occasionally. Mild pharyngitis is not an uncommon occurrence. Other signs and symptoms in rubella include mild conjunctivitis, sore throat, coryza, cough, and headache.

The duration of illness in uncomplicated rubella varies considerably. Most patients would continue normal activity if the rash were not

present. Full return to normal activity usually occurs within 3 days. A few adults are bothered by persistent headache, eye pain, and pruritus for 7 to 10 days.

The white blood cell count in rubella tends to be low. Schiff and colleagues⁵⁰⁶ found leukopenia in all nine volunteers. Their leukopenia paralleled the pattern of fever, with onset occurring 24 hours before the rash manifested and persisting for 4 to 5 days. Before rubella could be confirmed by specific serologic and virologic methods, many experts thought that rubella could be confirmed accurately by characteristics of the white blood cell count.^{272,297} Leukopenia was found at the onset of disease; the total count rose to a high-normal value during a 10-day period. Relative neutropenia was reported by Hynes²⁹⁶ in many patients; one patient had a neutrophil count of 868 cells/mm³ on the first day of illness.

Plasma cells or Türk cells, or both, were seen in all cases of acute rubella studied by Hynes²⁹⁶ and Hillenbrand.²⁷² A Türk cell is a developing plasma cell that is 25 to 40 µm in diameter and contains a 15- to 30-µm nucleus. The nucleus has two to five prominent nucleoli and a well-defined, light reticulum. The cytoplasm often is vacuolated. Twenty-five percent of the patients studied by Hynes²⁹⁷ had elevated erythrocyte sedimentation rates during the first week of illness.

Complications

Joint involvement. The incidences of reported cases of arthritis and arthralgia vary considerably across studies.^{37,94,212,236,306,335,534,592,623} Arthralgia and arthritis occur more commonly in adults than in prepubertal children. Women are afflicted more often than are men. In a large outbreak in Bermuda in 1971, 42% of 125 patients studied complained of joint pain or discomfort.³⁰⁶ Three patients had swelling of the joints. The prevalence of joint symptoms increased from 18% in the 0- to 9-year-old age group by approximately 20% increments per decade; 73% of those older than 30 years had symptoms. Joint complaints were more common in females than in males older than 10 years of age. This difference was most marked in the 10- to 20-year-old age group. Landrigan and associates³³⁵ studied the location of joint symptoms in adolescents and found that the fingers were involved most often; the knees and wrists were also commonly implicated.

Yanez and associates⁶⁴³ studied 11 patients with rubella arthritis. In all instances, multiple joints were involved. The onset of arthritis occurred 1 to 6 days after the beginning of the exanthem and lasted 3 to 28 days (mean, 9 days). The erythrocyte sedimentation rate was elevated in three of seven cases, and one patient had markedly positive latex test results. The white blood cell count was below 5000 cells/mm³ in five of seven patients. One woman had bilateral carpal tunnel syndrome. Four children with transient carpal tunnel syndrome accompanying rubella virus infection have been described.⁴⁵ Panush⁴³⁰ identified serum hypocomplementemia with rubella arthritis in a 25-year-old woman.

The possibility that rubella viral infection is related to rheumatoid arthritis has been studied on several occasions.^{51,146,365,418,426} Martenis and colleagues³⁶⁵ described a 21-year-old woman in whom rheumatoid arthritis developed after typical rubella with arthritis. Deinard and associates¹⁴⁶ found that all serum specimens from 80 patients with rheumatoid arthritis contained rubella HI antibody. In contrast, only 86% of an equal number of nonarthritic controls and a group of people with other forms of arthritis had measurable rubella antibody titers. Ogra and associates⁴¹⁸ found that patients with juvenile rheumatoid arthritis had IgM and IgG serum rubella antibody levels that were four to six times higher than those observed in controls during rubella infection. They also found specific staining for rubella virus antigen in the synovial fluid of 33% of these patients with juvenile rheumatoid arthritis. Grahame and associates²²⁵ repeatedly recovered rubella virus from the synovial fluid of six patients with inflammatory oligoarthritis or polyarthritis during a 2-year period.

Neurologic manifestations. Encephalitis is a rare complication of rubella.* Sherman and colleagues⁵³¹ reported six cases of encephalitis in an epidemic during the spring of 1964 that involved approximately 30,000 children. This rate of encephalitis (one of 5000 cases) is similar

*References 4, 29, 53, 110, 120, 142, 163, 364, 380, 403, 483, 531, 547, 610, 632.

to the rate of one of 6000 reported in Detroit in 1942.³⁶⁴ Rubella encephalitis is clinically similar to encephalitis from measles virus infection but is thought to be less severe. Overall, the estimated mortality rate for rubella encephalitis is approximately 20%.¹⁸³ However, mortality and morbidity rates have varied considerably.

Although rubella encephalitis is a rare complication of rubella infection, rubella should still be considered in the differential diagnosis of encephalitis in unvaccinated individuals. Sherman and colleagues⁵³¹ reported that three of six children studied in Pittsburgh died of this complication during the spring of 1964, whereas in Atlanta during the same epidemic period, six patients recovered uneventfully. Rubella encephalitis typically is a self-limited illness with a favorable prognosis. Eighty percent of survivors tend to recover without any permanent sequelae.²³⁸

Guler and colleagues²³⁸ reported a case of rubella encephalitis from Turkey. A 9-year-old, unvaccinated boy was admitted with headache, fever, and loss of consciousness. He had bilateral retroauricular lymphadenopathy but never developed a rash. Serum and cerebrospinal fluid (CSF) were positive for rubella IgM antibodies, and serum IgG was detected 3 weeks later.²³⁸

Figueiredo and associates¹⁸³ reported a case of rubella encephalitis from Brazil. An 18-year-old, unvaccinated man had fever, nausea, severe headache, confusion, aggression, and a generalized tonic-clonic seizure. Eight days earlier, he had a rash and fever. Serum and CSF tested positive for rubella virus IgM and IgG antibodies. Rubella virus was also isolated and confirmed with polymerase chain reaction (PCR) positivity from CSF and peripheral blood mononuclear cells. Phylogenetic analysis showed that it was rubella virus of the 1a genotype.¹⁸³

The onset of encephalitis usually occurs 2 to 4 days after the rash appears, but occasionally, rash and neurologic symptoms occur at the same time. In other instances, the appearance of encephalitis is delayed as much as 1 week after the onset of illness. Examination of CSF usually reveals mild pleocytosis (20–100 cells/mm³); most cells are lymphocytes. The protein content is normal or slightly elevated, and the glucose concentration is normal.

Kenny and associates³¹⁴ studied seven survivors of rubella encephalitis 1 year after their illnesses and could find no significant loss of intellectual function. Five of the seven had abnormalities on electroencephalography, and two patients had minor neurologic abnormalities. Gibbs and colleagues²¹⁵ found abnormal electroencephalographic tracings for six of 45 children with uncomplicated rubella.

Other neurologic complications associated with rubella include progressive panencephalitis, carotid artery thrombosis, myelitis, optic neuritis, Guillain-Barré syndrome, and peripheral neuritis.* Figueiredo and colleagues¹⁸² also reported a case of Guillain-Barré syndrome associated with rubella from Brazil. An 18-year-old woman had fever, emesis, headache, neck pain, arthralgias, paresthesias, progressive weakness of her lower limbs, and left-sided facial paralysis. Six days earlier, she had rash, fever, cervical lymphadenopathy, and hepatomegaly. Rubella virus (genotype 1a) was isolated from CSF and peripheral blood mononuclear cells. Test results for serum IgM and IgG and CSF IgG antibodies against rubella were positive.¹⁸²

Numbness, tingling, and other symptoms consistent with neuritis commonly occur during rubella infection. Cuetter and John¹³⁶ studied 20 patients with complaints of neuritis accompanying rubella and could find no objective sensory deficits or nerve conduction abnormalities.

Wolinsky and colleagues,⁶³⁵ Lebon and Lyon,³⁴⁴ and others described a slowly progressive and fatal nervous system disorder associated with rubella infection that was similar to subacute sclerosing panencephalitis. This illness has occurred as a late manifestation of congenital rubella and has occurred in children who acquired their initial infection in childhood.⁵⁴

Thrombocytopenia. Thrombocytopenic purpura occurs in rubella at an incidence of one of 3000 cases.³¹ Children are afflicted more frequently than adults, and girls are affected more often than boys.^{22,31,240,303,357,404,428,549,615} The median interval between the onset of exanthem and the occurrence of purpura is approximately 4 days. Rash and purpura can develop simultaneously, but the hemorrhagic

manifestations often do not become apparent until 2 weeks after the exanthem develops. The illness usually is self-limited, but its duration varies from a few days to several months. Although deaths caused by hemorrhagic complications have occurred, recovery is the general rule.

Other complications. Myocarditis and pericarditis are rare complications of rubella.²⁰⁵ A 30-year-old woman had erythema multiforme exudativum and arthritis with apparent clinical rubella.²⁰² In an outbreak that involved 46 military recruits, testicular pain was a complaint of 25%.⁵⁰⁸

During a rubella epidemic in Japan in 1976 in which 79 patients were studied, 71% had mild catarrhal or follicular conjunctivitis.²⁵⁴ Six patients had epithelial keratitis that persisted for 2 to 7 days. Seventeen patients had preauricular lymph node swelling associated with their eye findings. During the same epidemic, 13 cases of hemolytic anemia (including two cases of hemolytic uremic syndrome) occurred after the patients had rubella virus infections.⁵⁹¹ During an epidemic of rubella in Japan, Sugaya and colleagues⁵⁶⁰ found that 7.5% of 241 patients had liver involvement.

Hepatitis has occurred in congenital rubella infections and acute infections in children and adults. Previously, severe hepatitis due to rubella had developed only in neonatal rubella infections. However, Figueiredo and colleagues¹⁸¹ reported for the first time a case of acute liver failure necessitating liver transplantation that was associated with rubella virus infection in a child. Test results for serum IgM and IgG antibodies against rubella were positive, and peripheral blood mononuclear cells showed cytopathic effects characteristic of rubella. The rubella virus genome was also detected in liver fragments, and rubella virus antigen was found in the cytoplasm of hepatic cells, which suggests that the virus was replicating in hepatic tissue. Rubella virus genotype 1a was identified. This case report suggested that rubella could be an unrecognized cause of acute liver failure in children and should be included in the differential diagnosis even if there is no prior exanthem history.

Rubella virus also has been reported to cause uveitis. De Visser and associate¹⁴⁵ reported that rubella virus could cause a clinical spectrum of ocular symptoms similar to those of Fuchs heterochromic uveitis (FHU) and might be involved in the pathogenesis of FHU. Ruokonen and colleagues⁴⁹¹ and Suzuki and associates⁵⁶² showed a strong association between FHC and intraocular antibody synthesis against rubella virus.

Congenital Rubella

From Gregg's original observation in 1941 of congenital defects in infants born to mothers who had rubella during early pregnancy until the pandemic of 1964, CRS was considered to include only some combination of abnormalities involving the eyes, ears, brain, and heart. However, observations in 1964, supported by new virologic and serologic techniques, revealed a far more complex CRS picture, and rubella syndrome was expanded to include many new anatomic findings and to acknowledge the reality of chronic, persistent infection.

Congenital rubella is the result of in utero fetal infection, which usually occurs during the first 12 weeks of pregnancy. The fetal infection usually is subacute or chronic and can result in abortion, stillbirth, congenital malformations, active processes at birth (e.g., thrombocytopenia, encephalitis, hepatitis), and rarely, infected infants without defects. Table 174.5 summarizes the clinical findings in congenital rubella, an estimation of their frequency, and their main characteristics.

Infant Death and Growth Restriction

The most common manifestation of congenital rubella, which is readily apparent at birth, is generalized restriction of growth.* Between 50% and 85% of these infants weigh less than 2500 g, although gestational age is normal. Infants with intrauterine growth restriction have one or more other stigmata of congenital rubella. After birth, those with intrauterine growth restriction often demonstrate continued growth restriction. In some instances, the failure to thrive is severe. Others have a normal growth pattern, but the child is proportionally small.

The mortality rate for children with congenital rubella is high during the first year of life. Death is related to congenital pneumonia, heart

TABLE 174.5 Clinical Findings and Characteristics of Congenital Rubella Virus Infection

Clinical Findings	Frequency (%)	Main Characteristics	Selected References
Death and Growth Restriction			
In utero death	10–30	Spontaneous abortion; stillbirth	230, 256, 494
Intrauterine growth restriction	50–85	Generalized effects	109, 193, 195, 256, 258, 287, 321, 348, 359, 376, 454, 489, 490, 507, 537, 574
Extrauterine growth restriction	10	Failure to thrive	258, 348, 376, 386, 436, 574
Neonatal and infant deaths	10	Resulting from pneumonia, heart disease, hepatitis, thrombocytopenia, failure to thrive, immune deficiency, encephalitis	126, 230, 256, 321, 490, 507, 574
Ocular Effects			
Cataracts	35	Present at birth	18, 34, 48, 126, 195, 214, 230, 256, 258, 287, 321, 322, 376, 406, 490, 501, 507, 536, 574, 588, 589
Retinopathy	35	Present at birth; usually does not cause problems with vision	48, 116, 125, 214, 230, 256, 287, 324, 325, 376, 588, 589
Microphthalmos	5	Usually associated with cataract	48, 170, 214, 287, 321, 490, 516, 574
Glaucoma	5	Usually present at birth	48, 125, 256, 258, 287, 321, 490, 516, 523
Cloudy cornea	Rare	Usually present at birth; resolves spontaneously	48, 258
Severe myopia	Rare	Usually present at birth; defect may progress	121
Hypoplasia of the iris	Rare	Present at birth	48, 488
Strabismus	5	Associated with other eye defects	257, 376, 417
Iridocyclitis	Rare	Transient; associated with other eye defects	536
Auditory Effects			
Nerve deafness	80–90	May be bilateral or unilateral; moderate or severe; often not recognized early	18, 50, 147, 170, 195, 230, 239, 256, 258, 332, 376, 392, 442, 447, 507, 523, 582, 589, 594
Central deafness	5	Often associated with other central nervous system defects	253
Middle ear damage	5	Usually associated with nerve deafness	477
Intraoral, Nasal, and Facial Effects			
Cleft palate or lip	Rare	—	170, 230, 507
Dental abnormalities	Rare	—	71, 237, 376
Micrognathia	Rare	—	285, 507
Chronic rhinitis	Rare	Transitory finding	447
High-arched palate	Rare	—	256
Neurologic Effects			
Motor defects	10	Associated with mental and other neurologic defects	376, 523, 646
Hyperirritability (tremors)	Rare	Transitory finding	482
Microcephaly	Rare	—	18, 258, 287, 376, 523, 574, 613, 628
Mental disabilities	10–20	Associated with other stigmata	121, 230, 253, 256, 374, 523, 559
Full anterior fontanelle	10	Transitory finding related to meningoencephalitis	123, 490
Meningoencephalitis	10–20	Transitory finding but may last for 1 year	148, 258, 321, 322, 447, 490, 536, 574
Spastic diplegia and quadriparesis	Rare	Associated with other stigmata	123, 148
Seizures	Rare	Frequently transitory and related to meningoencephalitis	148, 259, 376, 447
Hypotonia	Rare	Transitory defect	147, 148
Brain calcification	Rare	—	442, 444, 536, 574
Cerebral arterial stenosis	Rare	—	253
Anencephaly	Rare	—	507
Encephalocele	Rare	—	507
Meningomyelocele	Rare	—	559
Behavior disorders	10–20	Frequently related to deafness	121, 147
Central language disorders	5	—	177, 230, 621
Autism	5	—	121, 177, 253
Aqueductal occlusion or hydrocephalus	Rare	—	230, 497
Poor balance	Rare	—	147, 646
Progressive panencephalitis	Rare	Has onset during adolescence	585, 620

TABLE 174.5 Clinical Findings and Characteristics of Congenital Rubella Virus Infection—cont'd

Clinical Findings	Frequency (%)	Main Characteristics	Selected References
Cardiovascular Effects			
Patent ductus arteriosus	30	Frequently associated with other defects	18, 34, 171, 195, 256, 258, 263, 304, 322, 399, 523, 536, 574, 589, 617
Pulmonary arterial hypoplasia, supralvalvular stenosis, valvular stenosis, and peripheral branch stenosis	25	Frequently associated with other defects	195, 256, 258, 263, 304, 523, 535, 589, 617
Aortic stenosis	2–5		193, 263, 533, 607, 617
Ventricular and atrial septal defects	2–5		34, 523, 589, 617
Tetralogy of Fallot	2–5		170, 258
Myocarditis and myocardial necrosis	10		5, 15, 321, 399, 574, 617
Intimal fibromuscular proliferation of many arteries	5		169
Ventricular aneurysm	Rare		224
Pulmonary Effects			
Interstitial pneumonitis	5–10	May be acute, subacute, or chronic	47, 170, 258, 321, 322, 399, 442, 444, 447, 507, 536, 574, 628
Tracheoesophageal fistula	Rare		507
Respiratory distress	Rare	Secondary to acute pneumonia	376
Gastrointestinal Effects			
Esophageal atresia	Rare	—	507
Hepatitis	5–10	Associated with other evidence of disseminated disease	18, 170, 172, 258, 398, 552, 574
Obstructive jaundice	5	—	321, 322, 399, 482, 536
Chronic diarrhea	Rare	Related to failure to thrive and immune deficiency	447, 574
Pancreatitis	Rare	May lead to diabetes in later life	64, 156
Duodenal stenosis	Rare	—	150
Jejunal or rectal atresia	Rare	—	170
Genitourinary Effects			
Undescended testicle	Rare	Cause-and-effect relationship with rubella infection in doubt	376, 536
Polycystic kidney, ectopic kidney, renal agenesis, or bilobed kidney	Rare	Cause-and-effect relationship with rubella infection in doubt	170, 169, 379
Hypospadias	Rare	Cause-and-effect relationship with rubella infection in doubt	48, 195, 536
Duplication of ureter	Rare	Cause-and-effect relationship with rubella infection in doubt	34
Renal artery stenosis	Rare	—	375
Hydroureter and hydronephrosis	Rare	Cause-and-effect relationship with rubella in doubt	259, 442, 523, 536
Inguinal hernia	Rare	Cause-and-effect relationship with rubella in doubt	259, 442, 523, 536
Nephritis and nephrocalcinosis	Rare	—	536, 574
Testicular agenesis	Rare	Cause-and-effect relationship with rubella in doubt	170
Orthopedic Effects			
Bone radiolucencies	10–20	Radiolucencies in metaphyses of long bones	258, 376, 442, 454, 464, 467, 489, 490, 518, 613, 624, 628
Pathologic fractures	Rare	—	489 ^a
Bone deformities	Rare	—	104, 230, 356
Clubfoot	Rare	—	507
Myositis	Rare	Transitory defect	544

defects and myocarditis, hepatitis, thrombocytopenia, encephalitis, immune deficiency, and failure to thrive.

Eye Effects

Approximately one third of infants with congenital rubella have cataracts.* Cataracts may be bilateral or unilateral and are centrally located with a surrounding clear zone or diffuse. In most instances, cataracts are present at birth, but occasionally they are not observed until later in infancy. Retinopathy consisting of pigmentary defects occurs commonly in congenital rubella and is useful diagnostically, but it rarely adversely affects visual acuity. Microphthalmos occurs relatively frequently and usually is unilateral. Cataracts frequently are associated with microphthalmos.

Congenital glaucoma occurs in approximately 5% of congenitally infected infants. This defect usually is present at birth, but it often is overlooked. The diagnosis must be established early if sight is to be preserved.

Auditory Effects

Sensorineural deafness is the most common manifestation of congenital rubella, and most patients have some degree of hearing impairment.†

The hearing loss usually is bilateral but may be unilateral. Frequently, the only manifestation of congenital infection is deafness. Deafness is frequently overlooked in infancy, and children incorrectly are considered to be developmentally delayed. All children born to mothers who had rubella during the first half of pregnancy should undergo evaluation of their hearing several times during the first 5 years of life, regardless of whether they have other manifestations of congenital infection.

Neurologic Effects

Between 10% and 20% of all infants with congenital rubella have active meningoencephalitis at birth.* Manifestations of this infection include one or more of the following: a full anterior fontanelle, irritability, hypotonia, seizures, lethargy, and head retraction and arching of the back. Examination of the CSF reveals elevated protein and mild pleocytosis. Later neurologic disease, such as intellectual disabilities and motor retardation, can be related to the severity and persistence of the initial meningoencephalitis. Active central nervous system infection has been demonstrated for a year or more.

Behavior disorders occur commonly in children with deafness and often cannot be associated with apparent meningoencephalitis. Children with congenital rubella who have generalized retardation of growth and a proportionally small head often have normal intelligence. In

contrast, the prognosis for mental development of a child with true microcephaly is poor.

Chronic progressive panencephalitis has developed in a small number of adolescents with congenital rubella, similar to measles-related subacute sclerosing panencephalitis.

Cardiovascular Effects

In severe congenital rubella with multisystem involvement, myocarditis occurs and often is a cause of death.* Of the structural defects of the heart, patent ductus arteriosus (PDA) has been previously reported to be the most common. Although PDA may be the only lesion seen, two thirds of patients have other lesions. Historically, pulmonary artery stenosis has been considered the next most common defect and may involve the main pulmonary artery or its branches.

Pulmonary valvular stenosis is the third most common defect. Pulmonic valvular or arterial stenosis and PDA commonly occur together. However, a study by Oster and associates⁴²⁴ that reviewed studies from 1941 to 2008 that used cardiac catheterization or echocardiography to evaluate cardiovascular malformations in CRS reported different patterns. They found that branch pulmonary artery stenosis was more common (78%) than PDA (62%) in patients who had been evaluated by catheterization. The combination of branch pulmonary artery stenosis and PDA (49%) was more frequently found than branch pulmonary artery stenosis (29%) or PDA (13%) alone.

Other Manifestations

The other manifestations of congenital rubella can be separated into three categories: those related to active, persistent infection; structural defects; and delayed manifestations of congenital rubella.[†]

Manifestations related to active, persistent infection. Manifestations related to active, persistent infection encompass a broad constellation of clinical events that largely were unknown before the pandemic of 1964. Collectively, they frequently are called the *expanded CRS* and include interstitial pneumonitis, hepatitis, nephritis, bone radiolucencies, myositis, dermal erythropoiesis, chronic rash, thrombocytopenic purpura, hemolytic and hypoplastic anemia, immunologic deficiency, generalized lymphadenopathy, hepatosplenomegaly, meningoencephalitis, and myocarditis. Most infants with the expanded CRS have low birth weight, exanthem caused by thrombocytopenia or dermal erythropoiesis (or both), hepatosplenomegaly, and jaundice. Radiographs usually reveal long-bone radiolucencies. Respiratory distress caused by diffuse pulmonary disease and myocarditis occurs commonly, and meningoencephalitis usually is evident.

The duration of chronic infection in these infants varies. Approximately 20% of survivors still are shedding virus at 1 year of age. Between 10% and 20% of those with hepatosplenomegaly and thrombocytopenia die during the first year of life.

Structural defects. Other than deafness, eye defects, and cardiac anomalies (discussed earlier), the association of other malformations with congenital rubella infection is less well established. Malformations such as tracheoesophageal fistula, jejunal atresia, inguinal hernia, and others recorded in Table 174.5 occur frequently without evidence of in utero infection. Because they are seen only sporadically in infants born after maternal rubella infection, they may be chance associations rather than cause-and-effect relationships.

Delayed manifestations. Important delayed manifestations of congenital rubella that were not seen in early life are deafness, ocular damage, progressive rubella panencephalitis, and vascular effects such as hypertension.⁵²⁸ Endocrine delayed manifestations associated with congenital rubella include diabetes, thyroid disorders, early menopause, osteoporosis, and possible growth hormone deficiency.¹⁴⁰ Of particular importance is the association between endocrine abnormalities and autoimmunity.¹¹³

In one study of 201 deaf adolescents with congenital rubella, 23.3% had positive thyroid microsomal or thyroglobulin antibodies, and of these patients, 19.6% had thyroid gland dysfunction.

Patients with congenital rubella have an increased incidence of insulin-dependent diabetes mellitus.²¹⁸ In a 40-year observational study of 280 Japanese patients with CRS, only three of the patients developed insulin-dependent diabetes.⁵⁶⁸ HLA associations with diabetes in CRS have been reported. HLA A1-B8, which has been associated with insulin-dependent diabetes, has been found in many patients with congenital rubella who have diabetes (44%).²⁸¹ A review of literature by Gale²⁰⁷ supports prior reports that CRS predisposes to diabetes. However, Gale's review suggests that only 1% of patients with congenital rubella instead of 20% will eventually develop diabetes.²⁰⁷

Psychiatric disorders are also often found in patients with CRS and may be seen in up to one half of patients. Rates of intellectual disability have been reported to be as high as 42%, and 4.12% to 7.3% of patients with CRS also may have autism. Higher rates of psychosis have been found along with increased rates of behavioral problems, including impulsivity, self-injury, and aggression.²⁹³

DIAGNOSIS

Differential Diagnosis

Postnatally Acquired Disease

Because no pathognomonic finding exists for rubella, the clinical diagnosis in an individual case often is difficult to establish (see Chapter 58). However, as with other exanthematous diseases, the key to establishing a diagnosis is careful elicitation of historical data. Rubella is an epidemic disease with a high clinical rate of expression of exanthem. When proper investigation is performed, it is unusual not to find the contact case or other cases in the community. Season also is an important consideration. Rubella typically occurs in the winter and spring, whereas enteroviral exanthems, which are the greatest masqueraders in young children, occur mainly in the summer and fall.

The incubation period also is important in separating rubella from exanthems caused by common enteroviruses or respiratory viruses. In rubella, the incubation period is long (18 ± 3 days), whereas the period in the other illnesses usually is much shorter (3–7 days). Age also is important. Today, rubella mainly is an illness of adolescents and young adults, and enteroviral exanthems are uncommon findings in patients at these ages.

The nature of fever also is useful in establishing the diagnosis of rubella. Temperature higher than 38.5°C (101.5°F) is an unusual occurrence in rubella but common with enteroviral exanthems, measles, and *M. pneumoniae* infection. A history of rubella infection is not particularly reliable, but if a past illness can be documented by year, season, and symptoms, accurate information can be obtained. Useful characteristics of the rubella exanthem are its mild, erythematous, maculopapular, and discrete nature; marked pruritus in adolescents and adults; and an acneiform appearance on the face in adolescents.

Although suboccipital and posterior auricular lymphadenopathy is thought by some investigators to be pathognomonic, its presence in nonrubella exanthems often leads to undue concern. In a young child, suboccipital and posterior auricular lymphadenopathy occurs as commonly with enteroviral illnesses as with rubella. In young adults, however, lymphadenopathy is much more useful because the enteroviral differential consideration is less of a problem. Similar lymphadenopathy does occur with acquired toxoplasmosis, infectious mononucleosis, and *M. pneumoniae* infection.

A major problem in the differential diagnosis for adults is allergy. However, fever (even low grade), lymphadenopathy, headache, and eye pain, which are common events in rubella, occur rarely in contact or other simple allergies.

Congenital Rubella

Establishing the diagnosis of congenital rubella in infants with known maternal exposure usually is not difficult. However, examining an apparently normal child at periodic intervals during the first few years of life is important so that deafness and subtle neurologic defects are not missed. The diagnosis of congenital rubella after an uneventful

pregnancy is more difficult to make. All infants with evidence of intrauterine growth restriction or stigmata suggesting congenital infection should undergo virologic and serologic study for rubella and other infectious agents.

Determination of the amount of serum IgM can be useful in the study of infants with intrauterine growth restriction or those born to mothers in whom rubella or other infection was suspected to have occurred during pregnancy.⁵⁵⁴ Values greater than 21 mg/dL during the first week of life strongly indicate congenital infection, but normal values do not rule out congenital infection.

Specific Diagnosis

Postnatally Acquired Disease

Rubella viral infection can be diagnosed specifically by isolation of virus from nasal or throat specimens in AGMK or other sensitive tissue culture systems or by PCR^{36,128,129}; by the observation of a significant change in value of HI, ELISA, immunofluorescence, CF, or neutralizing antibody in two sequential serum samples; or by the demonstration of specific rubella IgM antibody in a single serum sample. The diagnosis of rubella usually is attempted by using a single serum test for identifying rubella IgM antibody.*

Commercial rubella IgM immunoassays are available, and their sensitivity and specificity ranges vary from 75% to 95% and from 85% to 100%, respectively.^{152,578} Determination of rubella-specific IgM antibody in saliva 7 to 42 days after the onset of illness also is sensitive and specific.⁴⁶³

Although these tests are practical, the specificity and sensitivity of all routinely used tests are not 100% accurate. False-positive results often occur and commonly lead to unnecessary interventions. When the diagnosis is critical, such as with suspected rubella in pregnancy, a wise approach is to study IgG antibody in paired sera collected 1 to 2 weeks apart in addition to determining IgM antibody levels. One of the problems encountered with diagnosing rubella infection with serum IgM antibodies is that only 50% of serum samples from rubella cases collected on the day of rash onset are positive for the virus. Work by Abernathy and associates¹ compared detection of rubella IgM from sera and oral fluids with detection of rubella RNA from oral fluids by real-time PCR (RT-PCR) taken within 4 days after rash onset from suspected rubella cases during a rubella outbreak in Peru in 2004 to 2005. They found that RT-PCR testing of oral fluid confirmed more rubella cases than IgM testing of serum or oral fluid during days 1 and 2 after rash onset. However, the methods confirmed approximately the same number of cases on days 3 and 4 after rash onset.

Unfortunately, a rise in IgG antibody titer and an IgM-positive test result can occur in reinfection and in primary infection. Because reinfection in a pregnant woman is not likely to lead to damage of the in utero fetus, distinguishing primary infection from reinfection is important and can be done by measuring the avidity of rubella IgG antibody.^{248,277,461} Rubella IgG avidity assays focus on the strength of the antigen-antibody interaction, which is different for first exposure to an antigen (e.g., primary infection) compared with a previous infection. In primary infection, the antigen-antibody interaction is low (i.e., low avidity), whereas in reinfection or prior infections, the antigen-antibody interaction is stronger (i.e., high avidity).⁵⁷⁹

Congenital Rubella

The best method for establishing a definitive diagnosis of congenital rubella is viral isolation or PCR. Specimens for viral culture or PCR should be obtained from the nose, throat, urine, buffy coat of blood, and CSF. Because of transplacental passage of maternal IgG, establishment of the diagnosis of congenital rubella in the neonatal period by serologic methods is fraught with difficulty. Usually, specific rubella IgM antibody can be demonstrated with currently available techniques. In questionable cases, follow-up studies comparing infant and maternal antibody values often establish the diagnosis. If the infant's value is the result solely of transplacentally acquired antibody, it should drop fourfold to eightfold by the time the infant reaches 3 months of age and continue to fall to

nondetectable values by 6 to 8 months of age. Because the antibody value in some congenital infections also may fall, disappearance of antibody in serum does not rule out in utero infection completely. In questionable cases, the study of IgG rubella antibody avidity may be useful.^{269,461}

The retrospective diagnosis of congenital rubella in late infancy and the second year of life has been difficult to make. However, researchers have shown that affected children have low avidity of specific IgG antibody, and a retrospective diagnosis of congenital rubella can be made by specific avidity assays.²⁶⁹ Rubella IgG peptide-based enzyme immunoassay and rubella immunoblot assay also are useful for the serologic diagnosis of congenital rubella during the prenatal and newborn periods.³⁷⁴ Newborns who were infected during the first 12 weeks of gestation have reduced levels of antibodies directed at the linear E1 epitope (SP15) and the topographic E2 epitope.

CDC investigators have identified serologic markers in school-aged children with CRS.²⁹⁵ The children had more rubella virus-specific IgG antibody and stronger C protein and E2 signals than children without CRS. Fetal rubella also can be diagnosed in amniotic fluid samples by RT-PCR.^{474,569}

Qualitative Demonstration of Rubella Antibody

The original screening method for rubella antibody was HI, which has been replaced by more rapid and easier tests involving enzyme immunoassay, erythrocyte agglutination, and latex agglutination. All are highly sensitive and specific.^{99,179}

TREATMENT

Postnatally Acquired Disease

Uncomplicated Rubella

No specific therapy is necessary or indicated for uncomplicated rubella. Starch baths may be useful for adults with troublesome pruritus. Affected patients should understand that they are contagious and that transmission of infection to a pregnant woman could have serious consequences.

Complications of Rubella

Arthritis sometimes can be severe in adults. When weight-bearing joints are affected, rest is encouraged. Symptoms readily respond to aspirin therapy; corticosteroids are not indicated. For patients with rubella encephalitis, care is supportive, employing adequate maintenance of fluids and electrolytes.

Thrombocytopenia usually is self-limited. However, severe bleeding has occurred on occasion. Splenectomy is not indicated. Corticosteroid therapy often is used, but with little evidence of specific benefit in rubella-infected patients. In patients who do not recover rapidly and in those with severe bleeding, treatment with intravenous immunoglobulin should be considered.

Care of Exposed Pregnant Women

Ideally, all pregnant women should have received rubella vaccine previously or been shown to have rubella antibody by an appropriate serologic test. If a pregnant woman is exposed to a person with rubella and the history of previous immunization or antibody status is unknown, an immediate blood specimen should be obtained and a rubella antibody test performed. If antibody to rubella is demonstrated, no action is necessary.

If IgG antibody is not detectable in a pregnant woman exposed to rubella, she is not rubella immune. A second blood specimen should be obtained 2 to 3 weeks later and tested for rubella antibody concurrently with the first specimen. If the second test result is negative, a third blood specimen should be obtained 6 weeks after exposure and tested again for antibody concurrently with the first specimen. A negative result for the second and third specimens indicates that infection has not occurred. However, a positive test result for the second or third specimen but not the first indicates seroconversion and provides evidence for recent rubella infection.¹²

Susceptible rubella-exposed women should undergo careful clinical observation for fever, lymphadenopathy, or exanthem for a 4-week period. If illness occurs, a nasal specimen should be cultured for rubella

*References 13, 23, 33, 35, 36, 73, 87, 95, 100, 131, 152, 167, 180, 190, 219, 283, 362, 382, 405, 437, 514, 538, 578, 601.

virus, and serum should be examined for rubella IgM antibody. A second serum specimen should be submitted for rubella antibody examination. If rubella antibody seroconversion is identified or specific IgM antibody is demonstrated, the risk of fetal infection and malformation is considerable. Because false-positive rubella IgM antibody test results are not rare occurrences, all tests that yield positive results should be repeated for confirmation (by another assay and in another laboratory if possible). Because IgM antibody can occur in reinfections and fetal risk is then minimal, determining the avidity of IgG antibody also may be useful.^{248,277,461} The patient should be advised, and therapeutic abortion should be discussed.

In situations of known exposure of a susceptible pregnant woman in which therapeutic abortion is not a consideration and exposure can be documented to have taken place within 72 hours, we think that 20 mL of immunoglobulin should be administered immediately. The use of immunoglobulin is controversial, but in certain controlled situations, it has been effective in preventing disease.^{56,388,503,596,644}

Care of Pregnant Women With an Exanthem Thought to Be Rubella

Previous rubella serologic study results for a pregnant woman with an exanthem thought to be rubella are extremely useful. If previous serum antibody has been confirmed, the mother should be reassured that the current illness is not likely to be rubella. However, because false-positive rubella screening results do occur, a wise approach is to carry out rubella serologic study and, when possible, viral culture. An acute-phase serum sample should be examined for rubella-specific IgM antibody. A second serum specimen should be collected 1 to 2 weeks after the disappearance of the rash. If rubella antibody has risen significantly or IgM antibody is demonstrated, it is highly likely that congenital infection has occurred and that anomalies may result. A wise approach is to confirm IgM positive test results and, if available, do IgG rubella antibody avidity study. In this circumstance, the woman should be counseled about therapeutic abortion.

If a previous serum rubella antibody value is not available, a serum sample should be collected immediately and another collected 2 to 3 weeks later. These sera should be examined as paired specimens for rubella antibody and analyzed for specific rubella IgM antibody. If a rubella antibody increase is demonstrated or rubella IgM is confirmed, rubella viral infection can be assumed, and the patient should be advised about the risk for congenital infection and the possibility of therapeutic abortion.

Care of Children With Congenital Rubella

Isolation Procedures

Most infants with congenital rubella remain actively infected at the time of birth, are contagious, and therefore should be placed in isolation. Room isolation and urine precautions are the major necessities. The isolated baby should be cared for only by people known to be seropositive for rubella. Because rubella viral shedding can occur for a year or more from some infants, isolation of infants with congenital rubella should be continued for this duration unless repeated viral cultures have proved negative. Recommendations from the 2015 *Red Book* indicate that contact isolation of hospitalized children with proved or suspected congenital rubella is indicated until they are at least 1 year of age, unless two cultures of clinical specimens obtained 1 month apart after 3 months of age are negative for rubella virus.¹²

After the child is discharged from the hospital, no special precautions are necessary in the household setting. However, the parents should be advised of the potential risk to pregnant visitors.

Neonatal Period

The clinical manifestations of congenital rubella are varied, and many infants exhibit no symptoms during the first few months of life. In these apparently asymptomatic infants, no particular management problems are encountered. In other neonates, symptoms of continued viral infection are readily apparent and frequently are severe. Pneumonia, thrombocytopenia, eye findings, heart defects, hyperbilirubinemia, and hepatosplenomegaly are important findings in these infants.

Although purpura and petechiae due to thrombocytopenia may be impressively severe in these infants, true hemorrhagic difficulties have

not been a major problem. Corticosteroid therapy does not seem to be indicated, but considering treatment with intravenous immunoglobulin may be worthwhile. Careful evaluation of the eyes is important. Of immediate concern is the search for corneal clouding because it probably indicates infantile glaucoma. Cataracts and retinopathy also should be sought carefully. Infants with glaucoma should be referred immediately for ophthalmologic evaluation and therapy. Children with cataracts or retinopathy also should be referred, but therapy for cataracts is best delayed until the child reaches a later age.

Respiratory distress due to extensive viral involvement should be managed similar to other neonatal respiratory disease: assisted ventilation and careful attention to arterial blood gas values and pH. Although jaundice due to congenital rubella infection rarely is severe, standard criteria for the treatment of hyperbilirubinemia should be followed. Newborns with pulmonary hypertension may respond to nitric oxide therapy.⁴⁶² Hepatosplenomegaly can be marked in some instances but is of no therapeutic concern.

Cardiac evaluation should be the same as for affected infants without rubella. Congestive cardiac failure should be treated vigorously. In malignant conditions (e.g., patent ductus arteriosus, coarctation of the aorta), lifesaving surgery should be contemplated.

Long-Term Problems

Deafness. Hearing disability is the most common abnormality after infection with congenital rubella; more than 80% of infected infants have some degree of hearing disability. In many instances, deafness is the only clinical manifestation of congenital rubella, and because the establishment of this diagnosis in early infancy is difficult, the diagnosis often is delayed. However, early diagnosis of deafness and institution of proper educational programs are the most productive measures in the long-term management of children with congenital rubella.

Poor medical advice often has been responsible for the delay in making an appropriate diagnosis and providing therapy. Any time that a mother suspects that her child is deaf, specific audiometric testing should be performed. Many general practitioners, pediatricians, and otolaryngologists think that hearing cannot be tested in infants. This concept must be discouraged vigorously. At proper centers, a severely deaf child can be recognized in virtually all instances.

If deafness is diagnosed, the child should be referred immediately to a training program. Information about training programs can be obtained from the Alexander Graham Bell Association for the Deaf (<http://www.agbell.org>) and the John Tracy Clinic (<http://jtc.org>). In virtually all instances, severely deaf children should be enrolled in an education program before or during the second year of life, and the child should be fitted with a proper auditory amplification device. Although deafness in congenital rubella is sensorineural, a surprising finding is that conduction defects also occur in many older children, for whom other aspects of otolaryngologic care may be indicated.

Eye problems. All children with eye problems (i.e., cloudy cornea, glaucoma, cataracts, retinitis, or strabismus) should be referred at an early age for ophthalmologic evaluation. Glaucoma requires immediate attention. Decisions about cataract surgery should be left to the discretion of the ophthalmologist, but they usually can be deferred until after the end of the first year. Retinopathy, although frequently impressive on ophthalmoscopic examination, rarely causes much visual defect. Strabismus is managed as it is in children without rubella. Advice on eye problems in congenital rubella can be obtained from the American Foundation for the Blind (<https://www.afb.org/default.aspx>).

Heart problems. Congenital heart disease due to in utero rubella infection should be managed as heart disease is in children without rubella. The children should be referred to cardiac centers where sophisticated diagnostic techniques and cardiac surgery facilities are available for correctable lesions.

Musculoskeletal problems. Isolated musculoskeletal defects are relatively uncommon findings in congenital rubella. However, when the symptoms indicate, referral to a cerebral palsy clinic is useful for specific therapeutic modalities and for the camaraderie of group therapy for the children and parents.

Central nervous system problems. Careful analysis of the available data suggests that many infants who have been labeled intellectually disabled

are instead children with auditory or visual defects who have not had proper diagnosis and training for their handicaps. No child with congenital rubella should be labeled mentally subnormal until extensive audiologic and ophthalmologic investigations and perhaps specific therapy have been performed.

Immunologic defects. A few children with congenital rubella have specifically low levels of serum IgG. These infants have continued, systemic viral infection and fare poorly. Although outcome studies are not available, administration of immune serum globulin (i.e., intramuscular or intravenous immunoglobulin) to these infants periodically seems prudent.

Multiple handicaps. Children infected in utero with rubella virus often suffer from one or more of the handicaps mentioned. Care of these infants and children requires many different resources and modalities of therapy. Frequently, the physician is the one who must coordinate the diagnostic and long-term educational efforts that are necessary for optimal progress of an affected child.

In addition to the Alexander Graham Bell Association for the Deaf, the John Tracy Clinic, and the American Foundation for the Blind, several agencies can help physicians or the parents of congenital rubella children: United Cerebral Palsy Research and Educational Foundation (<http://www.ucp.org>), Easter Seal Research Foundation (<http://www.easterseals.com>), The Arc of the United States (<http://www.thearc.org>), and Maternal and Child Health Division, Department of Health and Human Services (<http://mchb.hrsa.gov>).

PREVENTION

Active Immunization Using Live Attenuated Rubella Virus Vaccine

In 1969, three rubella vaccines were licensed for use in the United States: HPV-77:DE-5 (i.e., duck embryo), HPV-77:DK-12 (i.e., dog kidney), and GMK-3:RK33 Cendevax (i.e., rabbit kidney) strains.^{470,622} Use of the HPV-77:DK-12 vaccine was later discontinued because a higher rate of joint complaints was reported after vaccination with this strain.

In 1979, the RA 27/3 (i.e., human diploid fibroblast) strain, Meruvax-II, was licensed for use in the United States. The RA 27/3 rubella virus vaccine is the only vaccine currently licensed for use in the United States. The RA 27/3 rubella vaccine is a live attenuated virus vaccine. The virus used was first isolated from a rubella-infected aborted fetus from the Wistar Institute in 1965. Attenuation of the virus was achieved by 25 to 30 passages in tissue culture, using human diploid fibroblasts. This vaccine does not contain any duck, chicken, or egg protein. The rubella vaccine is available in combination with measles and mumps vaccines as MMR or combined mumps, measles, and varicella vaccine as MMRV (ProQuad). The single-antigen rubella vaccine is not available for use in the United States.

The MMR and MMRV vaccines are distributed as a lyophilized (freeze-dried) powder and require reconstitution with sterile, preservative-free water. These vaccines contain trace amounts of human albumin, neomycin, sorbitol, and gelatin.⁸⁸ Vaccination can be expected to produce antibodies in more than 95% of those immunized.^{21,353,450,505,543,611,616,619} Antibody titers after RA 27/3 vaccination are slightly lower than those after natural infection, but they have been demonstrated to persist for an 11- to 15-year period with a pattern similar to that occurring after natural infection, even in the absence of reexposure to rubella virus.^{43,290,450}

Because of universal immunization practices, indigenous rubella has been eliminated in the United States and from the Americas.^{69,85,89,468,471} Finland's vigorous two-dose immunization program also resulted in the elimination of indigenous rubella.^{440,441}

Recommendations for Use

Complete information about rubella immunization is available in the most recent recommendations of the Immunization Practices Advisory Committee of the US Public Health Service,^{90,82} the recommendations of the Committee on Infectious Diseases of the American Academy of Pediatrics,¹² and the vaccine manufacturer's product information.

Rubella vaccine is recommended for all children 12 months of age or older, adolescents, and adults, particularly women, unless otherwise

contraindicated. Vaccination of children protects them from rubella and prevents them from subsequently spreading it. Vaccination of susceptible postpubertal women confers individual protection from rubella-induced fetal injury. Vaccination of adolescents or adults in population groups such as those in colleges, places of employment, or military bases protects them from rubella and reduces the chance of epidemics occurring among partially immune groups.

Rubella vaccine should not be administered to infants younger than 1 year because persisting maternal antibodies may interfere with seroconversion. When rubella vaccine is part of a combination vaccine that includes measles antigen, it should be administered to children approximately 12 to 15 months of age. A second dose of rubella-containing vaccine is recommended at school entry, typically at age 4 through 6 years.⁸⁸ Children who have not received rubella vaccine at the optimal age should be vaccinated promptly. Because a history of rubella is not a reliable indicator of immunity, all children for whom vaccine is not contraindicated should be vaccinated.

Vaccination of all unimmunized prepubertal children, adolescents, and adult women of childbearing age must be emphasized. Because of the theoretical risk to the fetus, women of childbearing age should receive vaccine only if they are not pregnant and understand that they should not become pregnant for 28 days after receiving the vaccination.^{12,88}

Special attention should be focused on targeted immunization of at-risk postpubertal males and females, especially college students, military recruits, recent immigrants, health care professionals, teachers, and child care providers. People born in 1957 or after who have not received at least one dose of vaccine or who have no serologic evidence of immunity to rubella should be immunized against rubella.¹⁴ Educational and training institutions such as colleges, universities, and military bases should seek proof of rubella immunity (i.e., a positive serologic test result or documentation of previous rubella vaccination) from all students and employees of childbearing age. Nonpregnant women who lack proof of immunity should be vaccinated unless contraindications exist.

For the protection of susceptible female patients and female employees, people working in hospitals and clinics who may contract rubella from infected patients or who, if infected, could transmit rubella to pregnant patients should have serologically demonstrated immunity to rubella or should receive the vaccine.

Routine premarital serologic testing for rubella immunity could enhance efforts to identify susceptible women before pregnancy. Prenatal or antepartum screening for rubella susceptibility should be undertaken and vaccine administered in the immediate postpartum period—before hospital discharge. Previous administration of anti-Rh0(D) immunoglobulin (human) or blood products is not a contraindication to vaccination; however, 6- to 8-week postvaccination serologic testing should be performed for confirmation of seroconversion in those few who have received the globulin or blood products. Obtaining laboratory evidence of seroconversion in other vaccines is not necessary. The 2015 *Red Book* provides updated guidelines for the minimum recommended interval for rubella vaccination after receiving immunoglobulin.

No evidence has shown that live rubella virus vaccine given after exposure prevents illness or that vaccination of a person incubating rubella is harmful. Because postexposure vaccination can theoretically prevent illness if administered within 3 days of exposure and protect a person in the event of future exposure, postexposure vaccination is usually recommended unless otherwise contraindicated.¹²

Adverse Reactions

Vaccination of young children rarely is associated with symptoms. However, mild fever, rash, lymphadenopathy, and upper respiratory tract symptoms occasionally have been observed. Fever develops 6 to 12 days after immunization in approximately 5% to 15% of children receiving the MMR or MMRV vaccines. Rash may occur in approximately 5% of those immunized, and mild lymphadenopathy has been frequently observed. A twofold increase in febrile seizure risk has been observed among children vaccinated with the combined MMRV vaccine 5 to 12 days after immunization. In children 12 through 23 months of age, febrile seizures occur more frequently after administration of the MMRV

vaccine (seven to nine of 10,000) than the MMR and varicella vaccines (three to four of 10,000) given separately. One additional febrile seizure may be expected to occur per 2300 to 2600 of the children immunized with the MMRV vaccine.^{12,300,318}

More severe reactions have occurred rarely in children but have been an occasional problem for adults. Most of these complications were associated with the previously available vaccines, but complications with the RA 27/3 vaccine also have been reported.^{21,161} Particularly troublesome are arthralgia and arthritis.* These symptoms occur most commonly in adults and have been seen more often in women than men.⁸⁸

Joint pain, which is typically localized to smaller, peripheral joints, has been found in approximately 0.5% of young children. Joint involvement typically begins 7 to 21 days after immunization and is considered to be a transient reaction.^{12,88} Arthralgia develops in approximately 25% of susceptible postpubertal females after they have received the RA 27/3 vaccination, and approximately 10% have had arthritis-like signs and symptoms.^{40,235,455} Infrequently, chronic or recurrent arthralgia, sometimes with arthritis or neurologic symptoms, including paresthesias, carpal tunnel syndrome, and blurred vision, have developed in susceptible vaccinees, primarily adult women.^{90,291} One group of investigators reported the frequency of chronic joint symptoms and signs among adult women to be as high as 5% to 11%^{575–577}; however, some data from the United States and other countries suggest that these complications caused by RA 27/3 vaccine are rare or perhaps nonexistent.^{127,189,198,262,414,539,545}

Patients with juvenile idiopathic arthritis (JIA) have been safely vaccinated with the rubella vaccine. However, a case report from Korematsu and colleagues³²⁰ describes an 11-year-old girl with systemic JIA, previously in remission for 4 years, who then developed an abrupt and severe relapse with congestive heart failure 5 days after receiving the rubella vaccine. The study authors suggested that the exacerbation of the patient's systemic JIA might have resulted from molecular mimicry between the rubella virus and her JIA.

Other complications, mainly with vaccines other than RA 27/3, include polyneuropathies (i.e., catcher's crouch, carpal tunnel syndrome, neuritis, and myeloradiculoneuritis),^{102,108,217,245,316,413,498} marked lymphadenopathy (J. Cherry, unpublished data, 1967–1976), vasculitis, and myositis.²⁵²

Geiger and associates²¹³ reported a persistent rubella virus infection in a 16-year-old boy with acute lymphoblastic leukemia in remission who was vaccinated. The virus was identified in the patient's peripheral blood mononuclear cells 8 months after immunization. In contrast, persistent infection could not be demonstrated in 10 children with symptomatic human immunodeficiency virus type 1 (HIV-1) infection.¹⁹⁷

Cheong and colleagues⁹⁸ reported a fatal case of disseminated tuberculosis in a 14-year-old girl, which occurred immediately after a measles-rubella vaccination. Previously, the exacerbation of tuberculosis infection related to measles-rubella vaccine was reported only for severely immunocompromised patients. Although natural measles infection has been known to potentiate other infections such as tuberculosis, no evidence has shown that measles-rubella vaccinations may accelerate the progression of tuberculosis.

Other adverse reactions that occur after immunization with MMR or MMRV have been primarily associated with the measles, mumps, and varicella components of the vaccine. Particular focus has been placed on the risk of immune thrombocytopenia purpura after MMR immunization.^{194,363} Chapter 245 offers details on other adverse reactions associated with the MMR and MMRV vaccines.

Contraindications

Administration of live rubella virus vaccine is contraindicated in women who are pregnant; in individuals with altered immune states, such as immunodeficiency, leukemia, lymphoma, and generalized malignant disease; and in patients treated with high doses of corticosteroids (≥ 2 mg/kg per day or >20 mg/day for 14 days or more), alkylating drugs, antimetabolites, and radiation.

Fever is not a contraindication to immunization, and children with mild illnesses such as upper respiratory tract infections can receive

immunizations. However, immunization should be delayed until recovery in cases of moderate to severe acute illnesses.^{12,88} A personal or family (i.e., sibling or parent) history of seizures of any cause is a precaution for MMRV vaccination because these children may have an increased risk of febrile seizures. This caveat does not apply for children vaccinated with MMR and varicella vaccines administered separately.⁸⁸ Rubella immunization in most instances should be deferred after the administration of blood products, including immune serum globulin (see Chapters 245 and 246).

Inadvertent Rubella Immunization in Pregnancy

From January 1971 to April 1989, the CDC observed to term 321 known rubella-susceptible pregnant women who had been vaccinated with rubella vaccine within 3 months before or 3 months after conception.⁹⁰ Ninety-four women received HPV-77 or Cendehill vaccine, one received a vaccine of unknown strain, and 226 received RA 27/3 vaccine. None of the 324 infants born to these women had malformations compatible with congenital rubella, but five of the infants ($<2\%$) had serologic evidence of subclinical infection. From these data, the CDC estimated a 1.3% maximal theoretical risk of congenital rubella among women vaccinated with the RA 27/3 rubella virus vaccine within 1 to 2 weeks before and 4 to 6 weeks after conception.¹² Women who might have been inadvertently immunized with rubella during pregnancy should be counseled extensively regarding the potential risks to the fetus. However, these observations of outcomes do not necessitate pregnancy termination as a result of rubella vaccine receipt during pregnancy.¹²

Many other studies have investigated the risk of congenital rubella among women who have received the rubella vaccine during pregnancy and have confirmed its safety. Castillo-Solorzano and associates⁷⁰ collected data from 2001 to 2008 from more than six countries and 30,139 women who were pregnant or became pregnant within 1 month after receiving the rubella vaccine. Seventy infants (3.5%) showed positive rubella serology results, but none of the infants had features of CRS. The study authors concluded that the maximal theoretical risk for CRS after rubella vaccination of susceptible pregnant women was 0.2%.

A large study by Soares and colleagues⁵⁴² covering several states in Brazil investigated 22,708 women vaccinated during pregnancy and found 67 newborns (4.1%) showed evidence of congenital infection but none with CRS. Da Silva e Sa and associates,¹³⁶ Sato and associates,⁴⁸⁴ and Minussi and associates³⁸³ reviewed cases from Brazil and found low rates of congenital rubella infection (2%, 4.7%, and 6.7%) but no cases of vaccine-associated CRS. A smaller study from 2006 in Argentina by Pardon and associates⁴³³ also did not show evidence of CRS in infants born to women unknowingly pregnant during their mass rubella vaccine campaign. Nasiri and colleagues⁴¹¹ and Namaei and associates⁴⁰⁹ looked at pregnant women inadvertently vaccinated with rubella during pregnancy during Iran's 2003 mass vaccination campaign and found no cases of CRS.²⁹⁹

In conjunction with a nationwide measles-rubella vaccination campaign in 2001, the fetal risk associated with rubella vaccination during pregnancy was studied in Costa Rica.¹⁹ The study involved 1191 mother and child pairs, and no adverse pregnancy outcomes or cases of CRS occurred.

Passive Immunization

The use of immunoglobulin for the prevention of rubella has been controversial for many years.^{26,55,154,231,360,368,372,388,503,596} However, I believe that its use is indicated in certain circumstances. The specific indication for immune serum globulin is for the prevention of rubella in a woman thought to be susceptible to rubella who is in the first 20 weeks of pregnancy. If the exposure can be documented clearly as one to a specific person with rubella and immunoglobulin is given within 72 hours of that exposure, maternal disease and congenital infection likely can be prevented. However, if the exposure was more general (e.g., schoolteacher exposed to children in the school setting), the woman probably was exposed for a considerable time before she realized the exposure. Because immunoglobulin probably will be administered too late—well into the incubation period of her disease and after viremia—congenital infection is not likely to be prevented. The dose of immunoglobulin for the prevention of rubella during pregnancy is 20 mL given intramuscularly.

Quarantine and Disease Containment

Patients with rubella should not have contact with susceptible people until the rash has disappeared. Containment of rubella is a vital part of the prevention policy in the United States. Rubella is a reportable disease, and compliance is the obligation of all physicians and other health care professionals. Reporting cases of rubella enables public health workers to organize vaccination programs so that small outbreaks of disease can be prevented from developing into major epidemics. During an outbreak, those without evidence of immunity should be immunized or excluded from school or child care attendance.

Alphaviruses

175A ■ Eastern Equine Encephalitis

Gail J. Harrison • Theodore F. Tsai

Eastern equine encephalitis (EEE) is a highly pathogenic mosquito-borne viral zoonosis infection of humans, horses, and other vertebrates that occurs in North and South America and the Caribbean. It causes outbreaks of severe diseases in both humans and horses, with high mortality or neurologic impairment in survivors.

The disease EEE was first recognized in Massachusetts in 1831 when 75 horses died of viral encephalitis. The causative agent was isolated from infected horse brains in 1933, and in 1938 the first human case was identified when 30 children died of viral encephalitis in the northeastern United States. The vector and mode of transmission of EEE virus discovery was made by Dr. Charles William Lacaillade.³⁶

In North America, infections recur in highly focal, primarily coastal locations in association with the habitat of the ornithophilic mosquito *Culiseta melanura*, the enzootic vector. In the United States, most cases are along the East coast and Gulf coast states. Florida continues to have the highest occurrence of human cases.³⁸ It is also endemic in the northeastern United States.³⁸ Birds are the amplifying hosts, and humans

and horses are infected incidentally. Because it is a highly pathogenic virus in humans that may be disseminated in the population, it is considered a possible biologic agent, category B threat, that could be used against civilian populations.^{59,68}

ETIOLOGIC AGENT

EEE virus is an antigenically distinct member of the *Alphavirus* genus in the *Togaviridae* family. On the basis of nucleotide differences, it has been inferred that EEE and Venezuelan equine encephalitis diverged 1000 to 2000 years ago, with a subsequent division of EEE virus into North American and South American varieties.^{8,55,57} South American strains can be differentiated by monoclonal antibodies and by short-incubation hemagglutination-inhibition tests.

North American strains collected over a broad geographic and temporal span demonstrate remarkable genetic stability in one or two major lineages, with minor local divergences occurring within

isolated geographic loci. South American strains are genetically heterogeneous. They have been isolated in northward-migrating birds captured in the United States, but they have never been shown to become established.

ECOLOGY

Equine cases have been reported as far north as Quebec, Ontario, and Alberta provinces; in South America, EEE viral activity has been reported from the Caribbean, Mexico, Guatemala, Honduras, Panama, Colombia, Venezuela, Peru, Guyana, and Brazil and as far south as Argentina.^{5,9,25,67} The viral transmission cycles in the Caribbean and South America are not well characterized but apparently involve small mammals, birds, and *Culex (Melanoconion)* mosquitoes.^{1,25,48,49}

In North America, the distribution of virus activity closely follows the distribution of freshwater swamps on the Eastern Seaboard, Gulf Coast, and other inland areas. Florida, with abundant fresh-water wetlands, is the state in the United States with the most cases in humans.³⁸ The distribution of virus corresponds to the distribution of the principal enzootic vector, *C. melanura*.^{11,22,25} *C. melanura* feeds nearly exclusively on birds, so various epizootic (bridging) vectors are responsible for infecting humans and horses.^{21,22,29–31,38,40,43,44,65} Numerous species may be involved, including *Coquillettidia perturbans*, *Aedes sollicitans*, *Aedes vexans*, and *Aedes canadensis*.

In 2011, expansion of EEE virus to northern New England was observed. Bites from mosquito *C. perturbans*, as well as *C. melanura*, feeding on both avian and mammalian hosts including humans, may both be important in the epidemic/epizootic transmission of EEE virus, according to recent insights of the recent emergence and expansion of the virus into northern New England.^{48,49}

The bird species most commonly associated with *C. melanura* feedings and potentially responsible for this spread include the American robin, tufted titmouse, common grackle, wood thrush, chipping sparrow, black-capped chickadee, northern cardinal, and warbling vireo. The wood thrush and American robin especially may play a dominant role in supporting EEE virus amplification and have been termed *superspreaders* of EEE virus in North America.^{48,49} Infection and viremia are subclinical in most native birds, whereas whooping cranes and exotic birds such as emus, house sparrows, ring-necked pheasants, Pekin ducks, and chukar partridges may become ill and die of infection.^{4,13,15,44,66,72} Outbreaks resulting in thousands of deaths have occurred in commercial pheasant flocks, in some instances perpetuated by cannibalistic pecking or preening of persistently infected quills.⁴ Illness and deaths in pigs, goats, calves, rodents, and other mammals also have been reported.^{26,47}

C. melanura is found in and near freshwater swamps, where larval stages breed in acidic waters associated with mucky peat soils. These foci (from north to south) are found in upland red maple, coastal white cedar, and southern loblolly bay biotypes.^{11,25}

The viral overwintering mechanism has not been elucidated, but the remarkable permanence of endemic foci is a strong argument for overwintering in local reservoirs, such as reptiles and amphibians.^{11,34,35,40,47} Serosurveillance in amphibians and reptiles has shown that snakes, including garter snakes, have high seropositive rates and support viremia with EEE virus, whereas frogs, turtles, and lizards have little or low rates of infection.³⁰

EPIDEMIOLOGY

EEE is a rare sporadic infection; historically, a median of three cases occurred annually in the United States⁴² (Fig. 175A.1). More recently, a mean of eight cases per year (range, 3–21) have been reported to the ArboNET, Arboviral Diseases Branch, of the Centers for Disease Control and Prevention (Fig. 175A.2).

The states with the highest rates of infection show an average annual incidence of less than one per 10 million (Fig. 175A.3). EEE has been reported to occur in at least 17 states in the United States and is most commonly reported from Massachusetts, New Hampshire, and Florida (Fig. 175A.4).

However, these estimates obscure the remarkably consistent and focal distribution of cases on the Atlantic and Gulf Coasts, from Ontario

to Texas, and in isolated pockets of activity inland.^{5,9,20} For example, until 1995, all human cases in Massachusetts had occurred east of Highway 495 in Essex, Norfolk, Plymouth, Bristol, and Middlesex counties; the six southernmost counties account for most of the epizootic activity in New Jersey; and foci of EEE viral activity recur in upstate

FIG. 175A.4 Eastern equine encephalitis (EEE) virus neuroinvasive disease cases reported by state, 2004–13. EEE cases have been reported in 17 states, with Massachusetts, New Hampshire, and Florida reporting the most cases. (Courtesy Centers for Disease Control and Prevention. Available at: <https://www.cdc.gov/easternequenecephalitis/tech/epi.html>.)

New York counties near Syracuse, southwestern Michigan, northeastern Indiana, and northeastern Florida.^{12,20,29,31,35} Outbreaks of human cases caused by North American viral strains have been reported from Jamaica, Trinidad, and the Dominican Republic.^{6,17,18} Isolated epizootics with sporadic human cases have occurred in South America.⁶⁷ The unpredictability of risk for EEE is underscored by the occurrence of a case in a United Kingdom tourist who had a brief itinerary in Massachusetts.³² Therefore history of travel should be obtained in patients with possible EEE who are diagnosed in nonendemic areas.

Viral transmission, reflected in equine cases, occurs all year in Florida, although the peak incidence is from May to September.⁷ Human cases have appeared as early as February and as late as in winter in December in Florida, with a peak occurring from June to August. In the Northeast, cases usually appear in late summer, from August to September, and as late as the third week in October.⁴² Cases in winter in other areas have also been described.⁶¹

Cases occur chiefly at the extremes of age. However, serologic studies performed during a New Jersey outbreak disclosed that infection occurs with equal frequency in all age groups, thus indicating that biologic responses to infection rather than factors associated with exposure were responsible for the lower attack rates in young and middle-aged adults.²⁷ The ratio of inapparent infections to cases was highest in the middle years of life (29:1) and lowest in children younger than 4 years (8:1) and adults older than 55 years (16:1).²⁷ Immune-compromised hosts also are vulnerable to severe or fatal EEE.⁶² Family clusters were observed in this epidemic and in the 1947 Louisiana outbreak.³³ In the New Jersey study, family members of cases had twice the rate of inapparent infections as the general population did; and in the southern Louisiana outbreak, two fatal cases and two seropositive members were observed in the same family.^{27,33} Clusters of equine cases on a single premise are reported frequently.

Asymptomatic infections are uncommon occurrences, and long-term residence in an enzootic area leads to only a slight increase in population immunity. For example, even in an unusually active focus in southern New Jersey, only 7% of persons who had resided there 45 years or more had neutralizing antibody.²⁷ In serosurveys of endemic foci in Massachusetts, evidence of past infections was found in 0.5% to 0.7% of residents,⁵⁶ and a postepizootic serosurvey of at-risk Connecticut pheasant farmers showed no evidence of infection.⁴⁵

Specific behavioral risk factors have not been described; however, residence, travel, and outdoor activity near swampy habitats have been reported anecdotally as possible contributing factors.

PATHOLOGY

Pathologic changes in the brain are consistent with severe meningoencephalitis with marked, diffuse cerebral edema and acute and chronic perivascular inflammation, and are characterized by lesions in the cortex, thalamus, basal ganglia, and brainstem, with cortical and deep gray

matter neuronal loss from mild to extensive focal necrosis.^{14,51} The areas on postmortem pathology correspond to lesions seen on neuroimaging, providing support that magnetic resonance imaging (MRI) findings represent virus-induced inflammatory and necrotic changes. Viral antigen is found predominantly in neurons and only occasionally in astrocytes.²³ Rare viral particles have been identified by electron microscopy in principally extracellular locations.^{3,39} Neutrophils predominate in cellular infiltrates in the meninges, vascular cuffs, and foci of tissue damage in the cortex and brain nuclei of patients dying acutely; at later stages, neutrophilic infiltrates are replaced by mononuclear cells.^{3,14,23,51} Immunohistochemical examination of one patient disclosed a predominance of helper T cells in perivascular infiltrates, with some B lymphocytes. The most intense inflammatory reaction occurred in areas where antigen-positive neurons were absent, presumably where cell lysis already had occurred. Perivascular macrophages contained cleared viral antigen, but antigen could not be demonstrated in vascular endothelial cells.²³

PATHOGENESIS

After peripheral inoculation of experimental animals, local viral replication occurs at a low level or may be undetectable. Viremia develops after this eclipse period, with disseminated infection of the spleen, liver, and kidneys noted in monkeys and guinea pigs and infection of the spleen, heart, and lungs observed in mice. Infectivity can be demonstrated in the brain only after viremia and infection in the viscera are established, thus suggesting that invasion of the central nervous system occurs by hematogenous spread.⁵¹ Neurologic injury is associated with vasogenic edema in the earliest stages and subsequently with virus-induced cytolysis and host inflammatory responses.²⁸

The immune response in humans presumably is similar to that observed in experimental alphavirus infections in mice, in which host resistance depends on rapid elaboration of a humoral immune response. Infection with EEE virus confers lifelong immunity, but does not confer significant cross-immunity against other alphaviruses, such as western equine encephalitis virus; flaviviruses, such as West Nile virus; or bunyaviruses, such as LaCrosse virus.

CLINICAL MANIFESTATIONS

EEE is a fulminant encephalitis with rapid progression to coma and death in one-third of patients. Fever appears to be an almost universal presenting sign. In infants and children, an abrupt onset of fever, irritability, stiff neck, and headache is followed within 1 to 3 days by lethargy, confusion, seizures, and coma.⁶² The often desperately ill infants may have a bulging fontanel, meningismus, high temperature, and generalized flaccid or spastic paralysis.^{2,19,24,71,73} Seizures are often present, with complex partial seizures, generalized tonic-clonic seizures, or both types reported, and some patients present with status epilepticus.⁶² The prodrome in adults and older children usually is brief, with nonspecific symptoms of fever, headache, and dizziness followed by clouding of the sensorium and rapid deterioration to coma. Remarkably, some patients have a prolonged prodrome lasting longer than a week, with a waxing and waning course of nonspecific symptoms, which may be associated with a better prognosis.^{54,56,62,71} Various neurologic deficits have been described; in some cases, unilateral seizures, hemiparesis, hemiplegia, and aphasia have indicated focal areas of involvement.^{16,50,54}

The peripheral leukocyte count usually is elevated with a shift to the left. White blood cell counts of 20,000/ μ L are typical, ranging as high as 60,000 with 55% to 89% neutrophils.⁵⁶ Cerebrospinal fluid (CSF) usually shows a polymorphonuclear pleocytosis with a total leukocyte count ranging from 500 to 2000/ μ L. The initial neutrophilic pleocytosis of 60% to 100% may persist into the second week before shifting to a predominance of mononuclear cells.⁵⁷ CSF protein level is elevated and glucose concentration is reduced in most cases.⁶² Erythrocyte counts higher than 500/ μ L are found in some cases.

Imaging studies disclose only cerebral edema in three-fourths of patients. However, focal rim-enhancing lesions and areas of low alteration with mass effect have been observed on computed tomography (CT) scans in the frontal cortex, thalami, midbrain, and lentiform nuclei.^{16,50,54}

CT of the brain may be abnormal as early as the first or second day of illness, with subtle attenuation abnormalities in the basal ganglia, cerebral cortex, and thalamus.⁶² MRI will also show evidence of brain abnormalities, which correlate with pathologic viral inflammation on autopsy, early in the illness. Isointense diffusion-weighted images and hyperintensity on apparent diffusion coefficient images early in the course of illness in one case suggested vasogenic edema in the T2-weighted hyperintense areas.²⁸ In one small case series, T2-weighted fluid-attenuated inversion recovery (FLAIR) hyperintensities, with linear areas of hyperintensity in the external and internal capsule and sparing of the lentiform nuclei, were described as a so-called parenthesis sign that may be suggestive of EEE.⁵² MRI also shows focal lesions in basal ganglia and thalami in patients with EEE.¹⁸ Electroencephalographic tracings with focal or background slowing have been associated with a favorable outcome, whereas disorganized background activity, a burst-suppression pattern, and high-voltage delta slowing have been associated with a poor prognosis.⁵⁶ EEG may also show epileptiform activity or subclinical status epilepticus.⁶² Mild nonencephalitic illnesses usually are not diagnosed. However, in the 1959 outbreak in New Jersey, fever, headache, nausea, vomiting, and sore throat were common symptoms in 19 patients who had serologic evidence of infection. One-third of the patients had illnesses sufficiently severe to motivate them to consult their physicians.²⁷ Other patients with bladder dysfunction, dysesthesias, weakness, and signs of myelitis have been described.^{10,41} One case of infection during pregnancy has been reported. The third-trimester infection was severe, but the woman recovered from encephalitis and coma and was delivered of an apparently normal neonate. Serologic studies of the neonate's blood were not performed. Infection with EEE also was reported to trigger fatal hemophagocytic lymphohistiocytosis in an infant.⁴⁵

PROGNOSIS AND SEQUELAE

The case-fatality rate is 33% among reported cases and is highest in elderly people; outcome is best in adults aged 20 to 59 years, in whom the case-fatality rate is 24%.³⁵ Patients with a long prodromal illness (>4 days) have a better prognosis, which is consistent with the protective effect of a peripheral antibody response in the preneuroinvasive phase.⁴⁶

Residual neurologic damage is observed more often in young children. In a Florida series, serious sequelae were seen in four of seven survivors younger than 5 years and in one of 10 survivors in other age groups.⁷ Similar findings were reported in a follow-up of epidemic cases in Massachusetts: seven of eight survivors younger than 3 years of age had neurologic sequelae, and only one of four surviving adults had residual.^{2,21} Neurologic impairment ranged from mild unilateral spasticity to profound mental retardation, seizure disorders, and quadriplegia. A report published in 2013 of children with EEE from Massachusetts and New Hampshire showed that most survivors with severe neurologic impairment at the time of acute recovery were able to regain substantial cognitive and motor skills with appropriate rehabilitation therapy.⁶²

DIAGNOSIS

A specific laboratory diagnosis usually is made from serologic studies. Isolation of virus from CSF is unusual. The virus should be sought from brain biopsy tissue or autopsy material. EEE virus grows rapidly in a variety of cell lines, including Vero A549 and MRC-5 cells, and causes widespread cytopathic effect in several days.⁶⁴ Specific identification of viral isolates can be accomplished rapidly by immunofluorescent or immunoperoxidase techniques. EEE virus has been identified by immunofluorescence and by electron microscopy in brain tissue.^{3,23,39} Viral antigen in viremic bird blood, infected mosquito pools, and infected equine brains can be detected directly by antigen capture enzyme-linked immunosorbent assay (ELISA). Polymerase chain reaction analysis of CSF has been reported but has not been evaluated extensively for routine clinical diagnosis.^{57,60} Testing of CSF for EEE is most often done at a state public health laboratory or the Division of Vector-Borne Diseases (DVBD) Laboratory at the Centers for Disease Control and Prevention (CDC).

Serologic testing is also available in many state and reference laboratories and is currently the preferred method for diagnosis in patients.

It also may be done at the DVBD laboratory at the CDC. Virus-specific IgM usually can be detected in acute serum and CSF samples, using antibody-capture ELISA.^{46,62} Indirect immunofluorescence, neutralization, and hemagglutination-inhibition also are sensitive procedures. Confirmatory virus-specific neutralizing antibodies by plaque-reduction neutralization assay is a serologic test available at health department laboratories. Antibodies often are present in the first week of illness. Neutralizing antibody appears 3 to 4 days after the onset of illness, and hemagglutination-inhibition (HI) antibody appears with almost equal rapidity.²⁷ Both HI and neutralizing antibodies appear to be long lived.²⁷ Complement-fixing (CF) antibody is slower to rise and can be noted 11 days after onset, with diagnostic fourfold rises often appearing only in the third week after onset.²⁷ The peaks of both HI and CF titers are observed 3 to 4 weeks after onset.²⁸ CF antibody declines more rapidly. Measurable CF antibodies were found in approximately 50% of persons infected 8 years earlier in one study, although the effects of reexposure could not be ruled out in this endemic area.²⁷ Research and development of an ELISA-array platform that detects five different encephalitis viruses (Japanese encephalitis virus, tick-borne encephalitis virus, equine encephalitis virus, Sindbis virus, and dengue virus) has shown it to be easy to use, sensitive and specific, and accurate and potentially will be widely available for clinical use in areas where these viruses cause disease.³⁷ Immune-compromised patients may not have an immunoglobulin M (IgM) or IgG antibody response to EEE, and diagnosis may require direct detection of the agent in CSF or brain tissue.⁶³

The low prevalence of EEE antibody in the general population suggests that detection of EEE viral antibody in the acute serum of a patient with encephalitis indicates a high probability of that diagnosis. Applying the Bayes theorem, if the "rate" of EEE is 1 in every 2000 cases of encephalitis, if HI antibody to EEE is present in 100% of cases in the first week of illness, and if the prevalence of HI antibody in the general population is 0.05%, the presence of EEE in a patient with encephalitis who has demonstrable EEE antibody in a single serum specimen is a certainty.⁶⁸ Thus the probability of the diagnosis is high when specific antibody is found in any (i.e., acute) serum specimen.

All EEE disease cases are reportable to the local public health department in order to recognize potential outbreaks and institute control measures.

DIFFERENTIAL DIAGNOSIS

The fulminant clinical course of EEE, the laboratory findings of neutrophilic leukocytosis and polymorphonuclear pleocytosis in the CSF, and focal findings on brain imaging may suggest bacterial cerebritis or meningitis as a working primary diagnosis until it is excluded with bacterial cultures. Because no specific antiviral therapy is available, EEE should be a diagnosis of exclusion, confirmed eventually with serologic and virologic testing, which may take several weeks or more to finalize. This should be done after every feasible effort has been made to diagnose and to treat empirically against bacterial meningitis and herpes simplex virus encephalitis, as well as after excluding other herpesvirus and arbovirus infections, influenza virus, enterovirus, rabies virus, and other infectious and noninfectious causes of encephalitis in humans. If exposure history is positive for endemic regions, Japanese encephalitis virus, tick-borne encephalitis, Sindbis virus, and dengue virus can all cause a similar clinical picture to EEE and should also be considered in the differential diagnosis.

TREATMENT

Specific antiviral treatment for EEE is unavailable. Therapy aimed at supporting cardiorespiratory function, homeostasis of fluid, electrolyte balance, and control of cerebral edema and seizures is indicated and may be lifesaving. Antiviral research and development initiatives have focused on agents with activity against EEE, but no specific antiviral agent is licensed for treatment of EEE in humans.⁵⁹ In case reports, intravenous immune globulin and glucocorticoids, as well as cyclophosphamide and interferon- α , were given for their potential immunomodulatory effects and were associated with survival.^{28,70}

PREVENTION

An effective killed vaccine is licensed for horses, but no human vaccine is licensed. An investigational killed vaccine, available under investigatory permit, is used to protect laboratory personnel.⁵⁷ Other vaccine candidates, such as a Sindbis/EEE virus chimeric vaccine and a recombinant EEE virus attenuated by internal ribosomal entry site control, have been tested in vitro and in animal models.^{53,69} Vaccination of the general public is not feasible as a public health measure because of the low incidence of disease.

Climatologic studies have shown a correlation between outbreaks and heavy rainfall in the summer of an epidemic year and in the preceding fall.^{34,40,42} Although such predictors would have considerable utility in guiding control measures, outbreaks of EEE have been too few for their validity to be tested. Isolation of Highlands J virus, which shares a common enzootic cycle with EEE virus, often peaks 2 to 3 weeks before the appearance of EEE virus in *C. melanura*.

Surveillance and public health interventions to prevent EEE in endemic areas have been shown to be economical when they are balanced against the direct and indirect costs of even one human case.⁶⁹ Infection rates in *C. melanura* of 0.39 per 1000 population have been highly predictive of risk for human cases in areas of Massachusetts surveyed during a 26-year interval.³² Larviciding of swampland to control *C. melanura* is difficult because of the large areas involved, the potential toxic effects in fish and other wildlife, and the relative inaccessibility of the larvae. Emergency application of adulticides to control epizootic vectors is indicated when viral, mosquito, and animal surveillance suggests a risk for epizootic transmission.

For the individual, public health advisories to avoid outdoor activity near enzootic foci and closure of campgrounds and parks in these locations may be necessary when viral transmission indices suggest a high level of risk. The use of repellents containing DEET, picaridin, IR3535, or oil of lemon eucalyptus on exposed skin or on clothing is recommended, and permethrin can be used on clothing as well. In addition, wearing long sleeves and long pants outdoors is recommended. Also, installation and repair of screens on windows and doors to keep

out mosquitoes should be done. To keep mosquitoes from breeding and laying eggs near habitats, removal of even small amounts of standing water is an important preventive measure. Also, avoidance of outdoor activity 1 to 2 hours after sunset, when many mosquitoes are most active, may reduce the risk for exposure from *Culex* mosquitoes; however, some vector *Aedes* species are daytime biters. "Avoid bites day or night" is a popular public health slogan to help prevent all mosquito-borne illnesses.

175B ■ Western Equine Encephalitis

Gail J. Harrison • Theodore F. Tsai

Western equine encephalitis (WEE) is an endemic and enzootic acute central nervous system (CNS) infection of humans, including children, and horses in the western part of the United States, Canada, Mexico, and parts of South America. In North America, *Culex tarsalis*, the principal mosquito vector, also maintains the virus in an avian enzootic cycle.^{5,81} WEE virus is currently classified as a Biological Safety Level 3 (BSL-3) agent because it is highly infectious and potentially may be transmitted via aerosol, and a Category B bioterrorism agent based on its moderate ability to disseminate in the population and produce serious disease in humans.⁶⁷

ETIOLOGIC AGENT

WEE and other alphaviruses (group A arboviruses) form a genus of principally mosquito-borne viruses in the family *Togaviridae*.^{50,71} Three of the eight viruses constituting the WEE antigenic complex are found in North America: Highlands J, Fort Morgan, and WEE viruses. Among these, only WEE virus is a human pathogen. Much of what is known about the molecular biology of alphaviruses has been inferred from studies of the Sindbis (the type species and a member of the WEE complex) and Semliki Forest viruses.

Alphaviruses are small, enveloped, positive-stranded RNA viruses. Virions are spherical and 69 nm in diameter (including the length of their glycoprotein spikes), with a lipid bilayer enveloping a nucleocapsid core containing the 11.7-kb RNA viral genome.⁶⁷ Glycoprotein spikes embedded in the viral envelope bind to cell membrane receptors and initiate infection by endocytotic fusion. The viral and lysosomal

membranes fuse in a pH-dependent step, and the viral nucleocapsid is released into the cell cytoplasm, where RNA and protein synthesis occurs. The 5' terminal two thirds of the RNA genome encodes four nonstructural proteins, and the 3' terminal third of the RNA genome encodes the three structural proteins. The 30-kDa nucleocapsid and two 50-kDa glycoproteins—E1 and E2—are translated as a polypeptide from subgenomic 26S RNA. The envelope proteins—E1 and E2—are assembled in trimers of a single E2 protein and an E1 dimer. Eighty such trimer spikes are arranged in an icosahedral lattice on the virion surface.¹² Capsid proteins assemble with the viral genome in the cytoplasm and then bud through the virally modified cell membrane and acquire an envelope.

The E1 glycoprotein possesses a group-reactive hemagglutinin and group-reactive epitopes linked to cross-protection and cell-mediated cytotoxic effects. E1 also mediates viral cellular membrane fusion and has been explored as a vaccine target.⁷² Epitopes on E2 are linked to cell receptor recognition, viral neutralization and clearance, and neurovirulence and cellular apoptosis.⁷⁶

Molecular genetic studies indicate that WEE virus arose more than 1000 years ago as a recombinant of eastern equine virus and an ancestral, now extinct, Sindbis-like virus, with the recombinant having acquired the neurotropic potential of eastern equine encephalitis (EEE) virus while retaining the antigenic and nucleocapsid characteristics of the nonneurotropic Sindbis virus.^{23,50,63,67,73,74}

Alphaviruses are thought to have originated in the New World with separate introductions, presumably by birds, to the Old World, resulting in establishment of the present-day Sindbis-like viruses and Semliki

Forest-related viruses. A slow rate of evolution, circa 10^{-4} nucleotide changes per year (vs. 10^{-2} /year for other RNA viruses), probably reflects the natural pressure on viruses constrained to replicate in both insect and vertebrate cells.⁷⁴

ECOLOGY

WEE virus is transmitted in an enzootic cycle to mosquitoes, birds, and other vertebrate hosts.^{54,53,59} Surveillance is usually accomplished by public health department vector control programs by collection of mosquitoes from endemic areas and testing for vector-borne viruses, such as WEE, using reverse transcription loop-mediated isothermal amplification (LAMP), or single or multiplex quantitative reverse transcription polymerase chain reaction (qRT-PCR) assays.^{9,77}

Horses and humans are dead-end hosts, but severe CNS infection may develop. Although WEE has been a public health and veterinary problem primarily in the western United States and Canada, the geographic range of the virus includes Mexico, Guyana, Brazil, Uruguay, and Argentina. Epizootics in horses, accompanied by small numbers of human cases, were reported in 1972 and 1983 in Argentina, where the virus apparently is transmitted by *Aedes albifasciatus* to introduced European hares and possibly birds. In addition, a distinct sylvatic subtype of WEE virus is transmitted in the subtropical Chaco province.^{4,8}

In the United States, the geographic distribution of the virus and *C. tarsalis*, its principal vector, includes the western and central United States, southern Canada, and Mexico. A related virus—Highlands J virus, isolated from *Culiseta melanura* in the eastern United States—overlaps in its range in the east central part of the United States. Highlands J virus causes encephalitis in horses and possibly in humans.⁴⁰

In the western region of the United States, *C. tarsalis* breeds in ground pools found on pasture lands; in irrigation wastewater; and at the margins of lakes, ponds, marshes, and flooded riversides. Some of these aquatic habitats are shared by birds that participate in the amplification of virus in nature.^{54,53,59}

The female mosquito becomes infected after feeding on a viremic bird (or mammal or possibly reptile). After an extrinsic incubation period of 7 to 9 days, when the virus propagates in the mosquito and the salivary glands become infected, the mosquito can transmit virus to other birds or mammals or reptiles (amplifying hosts) or to humans and horses (dead-end hosts).

Passerine (perching) birds, especially sparrows and finches, have proved to be particularly important in amplification of the virus. In midsummer, the mosquito shifts its host-seeking activity to mammals. The shift may be influenced by an increase in the defensive behavior of nestling birds, which are its preferred host. The shift corresponds temporally to the appearance of cases in horses and people and appears to be a critical element enabling *C. tarsalis* to function as both an enzootic and an epizootic vector. In California, an auxiliary *Aedes melanimon*-jackrabbit (*Lepus californicus*) cycle has been demonstrated.

The overwintering mechanism for WEE virus has not been elucidated. However, virus has been recovered from adult *Aedes dorsalis* mosquitoes collected as larvae from a coastal area of California, thus indicating a possible role for vertical transmission of the virus in mosquitoes in some locations. Arguments also have been advanced for viral overwintering in adult mosquitoes and in persistently infected mammals, birds, and poikilotherms (snakes, frogs, and turtles). Experimental infection of snakes (garter snakes) and tortoises show them to be susceptible to chronic infection with WEE virus.³ Seroepidemiology studies in the field show high prevalence of WEE virus antibody in reptile hosts, including snakes, lizards, turtles, and crocodiles. Reptiles, because of their low metabolic rate, may function as a reservoir host over the winter and transmit WEE virus to humans via an arthropod vector.³ In Canada, *Aedes* spp. and *Culiseta inornata*, which emerge in the spring before *Culex tarsalis*, have been proposed as early amplifying vectors.³⁹

Numerous climatologic and biologic indices with various degrees of predictive value have been shown to correlate with the occurrence of WEE outbreaks; these indices include vector population size, mosquito infection rates, and virus transmission rates to sentinel chickens or wild-caught sparrows. Such transmission indices are monitored in

surveillance activities by public health agencies; however, their sensitivity, specificity, and predictive value for forecasting epidemics have been difficult to evaluate because of the sporadic nature of outbreaks.⁷⁵ A retrospective analysis of a 21-year experience in California showed correlation between average daily numbers of *C. tarsalis* females and the occurrence of human encephalitis.⁴⁶ In a Texas study, house sparrow infection and antibody rates were the best predictors of human disease, and *C. tarsalis* light trap indices were of borderline significance.²⁹

Physical measures associated with the incidence of disease in humans or transmission of virus to sentinel species include the ambient air temperature, the snow pack in mountains providing runoff water, the river flow rate, the soil temperature inversion date (the date that the surface soil temperature exceeds the subsurface soil temperature), and the date when 50 or more days of 21°C (70°F) temperature have accumulated. Snow pack and river flow rate are associated with an abundance of irrigation water and flooding, which in turn are associated with the availability of breeding habitats and mosquito population size.^{10,28,54,55,53}

Longitudinal and intraseasonal observations show that high temperatures are associated with a reduced risk for human disease. High ambient air temperature (32°F [89.6°F]) decreases mosquito survival, adversely affects the competence of *C. tarsalis* to become infected with and to transmit WEE virus, and limits host-seeking activity.⁵⁸ In a model of global warming, higher temperatures are predicted to move the range of WEE viral transmission northward.^{54,55}

EPIDEMIOLOGY

WEE occurs sporadically and in epidemic form, principally in Canadian provinces and states west of the Mississippi River (Figs. 175B.1 and 175B.2). Infections occur mainly in rural areas, where water impoundments, irrigated farmland, and naturally flooded sites provide breeding habitats for *C. tarsalis*; however, the increasingly rare interface between vector mosquitoes and humans has resulted in a point seroprevalence of 1% to 2% even in locations where the virus is transmitted in an enzootic cycle.⁵⁸ The annual median number of cases between 1964 and 1995 was only four, and only four cases were reported between 1988 and 1997, a lower incidence than that for EEE. Historically, however, periodic outbreaks have led to scores or hundreds of cases (Fig. 175B.3).

Recurrent endemic and epidemic transmission was recorded in the Yakima Valley, Washington (1939–42); California's Central Valley (1939–52); the north central states and Canadian provinces, including Minnesota, North and South Dakota, Alberta, Manitoba, and Saskatchewan (1941 and 1975); and the high plains panhandle of Texas (1963–66).^{17,24,30,52,57} The largest outbreak on record, in 1941, resulted in more than 3400 human cases in Minnesota, North and South Dakota,

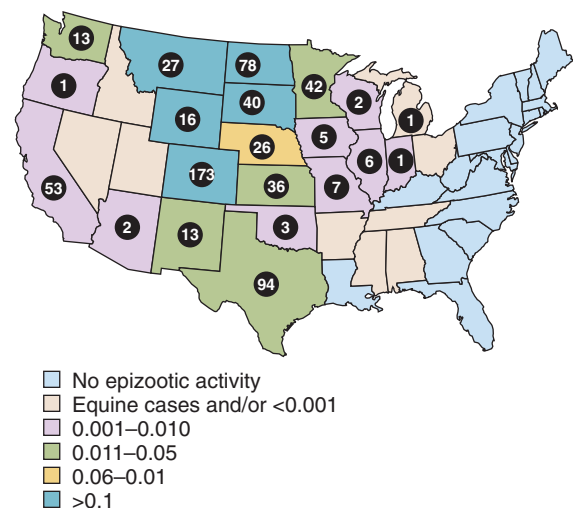

FIG. 175B.1 Reported cases and average annual incidence (per 100,000) of western equine encephalitis by state, 1964–95.

TABLE 175B.1 Western Equine Encephalitis Epidemic Attack Rates by Population Density^a

Population Area	Minnesota, 1941	Kern County, CA, 1952	Hale County, TX, 1963–66	Manitoba, 1975
Rural	15.8–22.0	149.2	2.62	10.8
Small town	2.3–5.6			2.4
Urban		28.5	1.0	0.9

^aPer 100,000 population.

FIG. 175B.2 Reported cases of western equine encephalitis by year, 1964–95.

FIG. 175B.3 Reported cases of western and eastern equine encephalitis by month, 1972–89.

Nebraska, Montana, Alberta, Manitoba, and Saskatchewan; equine cases were estimated to number in the hundreds of thousands. The outbreak centered in North Dakota, where the attack rate for cases in the state was 167 per 100,000.^{17,34} In 1952, an outbreak in California's Central Valley led to 348 reported cases, an incidence of 36 per 100,000 residents.³⁰ More recent outbreaks resulted in 277 cases in the central United States and Manitoba in 1975 and 40 cases in the central and mountain states in 1987.^{15,35,39}

Most cases occur between June and September (see Fig. 175B.3), often preceded by cases occurring in horses several weeks earlier. Surveillance of equine cases is a widely used approach to assess the risk for epidemic transmission. However, the low frequency of

FIG. 175B.4 Age- and sex-specific incidence of western equine encephalitis, Colorado, 1987.

laboratory-confirmed diagnoses, vaccination, and underreporting limit the precision of equine surveillance as a predictive marker.⁴⁹

- Several risk factors for acquiring WEE have been identified:
1. Attack rates usually are highest at the extremes of age² (Fig. 175B.4). The experience from the 1952 California outbreak showed that a third of cases occurred in infants younger than 1 year.^{30,54} Other reports confirm the bimodal pattern of an elevated risk in infants, a declining risk in children and young adults, and a gradual increase in risk in the elderly.
 2. Attack rates in males are twofold higher than those in females in every age group² (see Fig. 175B.2). Biologic differences in susceptibility to infection may account for the observed disparity in infancy, and greater occupational and recreational exposure outdoors might be responsible for the differences in adults. In the 1981 outbreak in Manitoba, 21 of 25 cases were in males; the four affected women were widows who maintained their premises alone.¹⁵
 3. Rural residence is associated with attack rates 1.5 to 5 times higher than those for urban residence (Table 175B.1). Counties lying in major river drainage areas and with more irrigated acreage have had the highest incidence of equine and human disease² (Fig. 175B.5).
 4. Agricultural occupation has been suggested as a risk factor in several studies.
 5. Length of residence in areas where WEE is endemic is associated inversely with a risk for developing illness. Acquired immunity, through asymptomatic or mild infection, accumulates with length of residence; in endemic areas, the point prevalence of specific antibody previously approached 20% by adulthood.^{54,53}

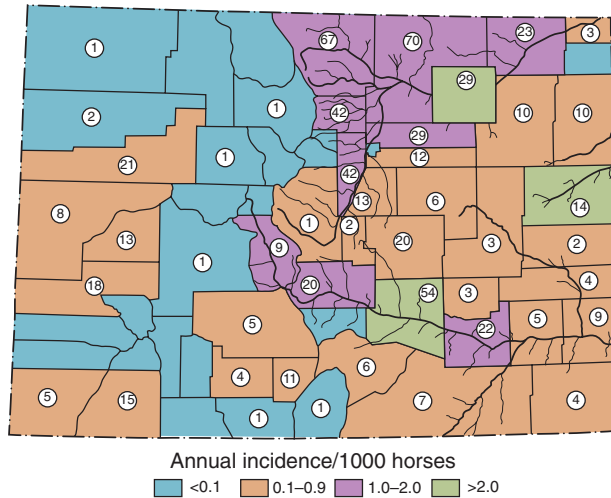

FIG. 175B.5 Reported equine cases and incidence of western equine encephalitis by county, Colorado, 1975–88.

CLINICAL MANIFESTATIONS

The clinical illness ranges from a nonspecific syndrome of headache and fever to aseptic meningitis, meningoencephalitis, and encephalitis with fatal outcome. The estimated case-infection ratio is 1:58 in children 1 to 4 years of age, but it declines to 1:1150 in adults.^{14,20,54,59}

The onset of illness typically is abrupt, with sudden fever, headache, malaise, chills, and nausea and vomiting,^{6,17,27,52} occasionally preceded by signs of an upper respiratory tract infection. Signs of CNS infection gradually become evident as dizziness, drowsiness, increasing headache, stiff neck, and disorientation develop during the course of hours or days. Infants typically have a sudden cessation of feeding, fussiness, fever, and protracted vomiting. The prodromal interval is abbreviated, and seizures and a lethargic unresponsive state develop rapidly.

On examination, patients appear somnolent and may have signs of meningeal irritation. The sensorium is depressed, and patients may alternate between agitation and somnolence. Generalized muscle weakness is present, and deep tendon reflexes are diminished. Focal neurologic signs suggesting herpes encephalitis have been reported in anecdotal cases^{1,7}; however, in the 1941 Minnesota outbreak, only three of 226 cases reported had unilateral weakness.¹⁷

In infants, the fontanelle may be tense or bulging, often accompanied by spastic paresis and generalized seizures. The frequency of seizures is related inversely to age; they occur with greatest frequency in infants younger than 3 months (75% to 80% of cases), whereas in 2- to 4-year-old children, seizures have been reported in 15% of cases.³⁸

The peripheral leukocyte count is unremarkable. Cerebrospinal fluid (CSF) obtained at an early stage in the illness generally exhibits normal glucose concentration, elevated protein level, and a leukocyte count between 10 and 300/mm³.^{3,35} Mononuclear cells usually predominate.

Five instances of late third-trimester infection in pregnant women have been reported to result in perinatal illness or encephalitis.^{13,14,38} The women's illnesses had an onset 0 to 10 days before delivery, and the infants became ill on the fifth and sixth postpartum days. Teratogenic effects of infection occurring earlier in gestation have not been reported for WEE virus but are suspected for other group A arboviruses.⁴¹

PATHOLOGY

Specific pathologic changes are confined to the CNS.^{6,35,44} On gross examination, the brain appears normal or may be congested and swollen, with minimal changes observed in the meninges. Microscopic lesions affecting gray and white matter appear throughout the brain but predominate in the basal ganglia. Disseminated small focal abscesses infiltrated with neutrophils are a distinctive feature. The vessels appear congested, and small focal hemorrhages or diffuse extravasations of erythrocytes are present along with neutrophilic infiltration of the

vascular wall and endarteritis. Vascular lumina may be occluded by endothelial proliferation and swelling.

Extensive patchy areas of demyelination are found throughout the brain. Older lesions appear as sharply circumscribed, punched-out plaques. Secondary microglial reaction in demyelinated areas is minimal.

The spinal cord is affected in the same fashion, with focal, perivascular, and diffuse lesions attracting both polymorphonuclear and mononuclear cells. Lesions predominate in the central gray matter.

PATHOGENESIS

Peripheral inoculation of experimental animals with WEE virus is followed by viral replication in various extraneural sites before invasion of the CNS (including the peripheral site of inoculation, viscera, muscle, and perhaps vascular endothelial cells) occurs, usually at areas where the blood-brain barrier is weak or absent.^{31,36,45,48,80}

Host resistance and recovery from infection depend chiefly on an effective antibody response. Antibody contributes to recovery by a variety of means, including viral neutralization and antibody-mediated restriction of viral gene expression.^{22,76} Interferon may contribute to containment of local viral spread in the CNS. Antibodies are protective and may be cross-protective to other alphaviruses. Antibodies to the E2 glycoprotein typically are virus specific and associated with neutralization and protection. Antibodies to E1 exhibit greater cross-reactivity with other alphaviruses.⁷¹ Immune serum given to monkeys prophylactically protects them from challenge with WEE virus, and passive protection has been demonstrated in monkeys inoculated with WEE virus and treated with immune serum within 24 hours.⁸⁰ However, immunotherapy in monkeys is uniformly unsuccessful in preventing death once signs of CNS infection have appeared. In guinea pigs peripherally inoculated with WEE virus, immunotherapy given within 24 to 48 hours of inoculation leads to survival of some animals and delayed death in others.⁴⁵ In one human case, passive immunization led to a delayed antibody response and was followed by the development of parkinsonism.²¹

The age-dependent virulence of specific Sindbis virus strains has been linked to the immaturity of the suckling mouse T- and B-cell repertoire. Fibroblasts from newborn but not weanling mice are susceptible to Sindbis virus infection, and viral infection of immature mouse neurons leads to apoptotic cell death. Mature neurons are protected against apoptosis by induction of the *bcl-2* oncogene, whose products convert the infection to a persistent nonlytic infection. Viral persistence in the brain of recovered mice is modulated by antibody.²²

PROGNOSIS

Major neurologic sequelae of WEE, including quadriplegia, hemiplegia, spasticity, intracerebral calcifications, developmental delay in children, and epilepsy, have been reported in approximately 13% of cases.^{16,18,27,82} The risk for development of serious neurologic sequelae in infants is triple that of other age groups, and 30% of recovered infants younger than 1 year remain seriously impaired.^{18,20,70} In infants younger than 1 year, seizures during the acute phase of illness were associated with a greater risk for poor long-term outcome, including continued seizures. Multiple intracranial calcifications were observed in one recovered infant with persistent seizures.⁶⁹ Minor psychiatric or neurologic deficits remained in approximately one fourth of children and adults monitored for 18 months after infection.¹⁸ Central apnea has been reported as a complication of encephalitis in two adult cases.⁷⁸

Parkinson syndrome has been a residual effect in at least 15 cases of adults surviving WEE.^{21,43,65,66} Its onset may be immediate or delayed for several years after recovery from the illness. Two retrospective investigations of patients with idiopathic Parkinson disease found no difference between cases and controls in seroprevalence to several arboviruses, including WEE virus.

The case-fatality rate in reported cases in the United States from 1955 to 1978 was 3% to 4%. In outbreaks in the central portion of the United States and Canada in 1941, 1975, and 1981, approximately 7% to 9% of patients died, with higher fatality rates in the elderly.

DIAGNOSIS

Virus rarely can be recovered from blood or CSF, but it can be isolated readily from the brains of patients who died of WEE. In a few attempts, WEE virus has been isolated from brain biopsy material; in principle, rapid diagnosis can be made by immunofluorescent identification of WEE viral antigen in brain biopsy tissue. The virus can be isolated readily, under BSL-3 containment precautions, in Vero cell culture or in suckling mice.⁶⁶ Nucleic acid–based sequence amplification and real-time reverse transcription polymerase chain reaction (RT-PCR) assays of CSF appear to be sensitive and specific. Duplex real-time RT-PCR assays that not only detect but also discern among alphaviruses have recently been developed.³²

Immunoglobulin (Ig) M capture enzyme-linked immunosorbent assay (ELISA) is the preferred serologic procedure and is available from public health laboratories and commercial reference laboratories.³⁷ IgM antibody usually is present in acute serum within a week after the onset of illness, and its presence is presumptive evidence of recent infection. IgM often can be detected in CSF before it can be identified in serum, and its presence, which indicates intrathecal production of antibody, confirms a recent CNS infection.³⁷ Identification of virus-specific IgM in serum and CSF by immunofluorescence also is possible; however, this approach is somewhat less sensitive than IgM capture ELISA and may be confounded by the effects of rheumatoid factor.

Hemagglutination-inhibition and neutralizing antibodies are elevated in the first week of illness in most cases, and a diagnostic fourfold rise in titer usually is observed in the second week. Complement-fixing antibody is slower to rise, with fourfold changes delayed until the third to fifth week after onset. The complement-fixation response may be blunted in older patients.⁷⁰

Neutralizing and hemagglutination-inhibition antibody titers have considerable longevity, with minimal decay noted 30 months after onset. In contrast, complement-fixing antibody is relatively short-lived, and its presence is a useful indicator of recent infection, particularly in endemic areas where long-term residents may have neutralizing and hemagglutination-inhibition antibody from previous exposure. Only two thirds of patients are estimated to show complement-fixing antibody 2 years after onset, and fewer than 15% have residual complement-fixing antibody after 5 years.⁷⁰

DIFFERENTIAL DIAGNOSIS

The clinical findings in patients with encephalitis seldom are sufficiently characteristic that a specific diagnosis can be made on clinical grounds alone. Fever, vomiting, signs of meningeal irritation, and confusion are nonspecific features of encephalitis and cerebral edema. Early symptoms in infants, such as fever, lethargy, and vomiting, may be even less specific.³³

Furthermore, the peak occurrence of arboviral infection in midsummer to late summer temporally overlaps the seasonal occurrence of other CNS infections by enteroviruses (e.g., echovirus 13, which recently has become epidemic in the United States), leptospires, free-living amoebae, and mosquito-borne Eastern equine encephalitis, Venezuelan equine encephalitis, and West Nile and St. Louis encephalitis.³⁷ CNS signs may be prominent in other summertime diseases, such as Rocky Mountain spotted fever, heat stroke, shigellosis, and lead encephalopathy. High priority should be given to establishing a specific diagnosis of treatable conditions, such as herpes simplex virus and enteroviral infection, while bearing in mind that dual arboviral and enteroviral infection has been reported.⁷

Other causes of CNS infection without an established summertime seasonality that also should be considered in the differential diagnosis include fungal, mycobacterial, and partially treated bacterial meningitis; brain abscess and infected subdural collections; bacterial endocarditis; toxoplasmosis; cat-scratch disease; and infections with rabies virus, mumps virus, herpes simplex virus, Epstein-Barr virus, human herpesvirus 6, adenovirus, lymphocytic choriomeningitis virus, and human immunodeficiency virus. Parainfectious disorders such as postinfectious viral encephalitis, acute cerebellar ataxia of childhood, mycoplasmal infection, neuroblastoma with opsoclonus, and Reye syndrome also

may enter into the differential diagnosis. Vascular disorders formed the largest single group of disorders mimicking herpes encephalitis in several studies. Drugs (e.g., trimethoprim-sulfamethoxazole, penicillin, isoniazid, phenazopyridine, ibuprofen, tolmetin, sulindac, and carbamazepine), high doses of bismuth, OKT3 antibody, and vidarabine also may cause aseptic meningitis or encephalopathy.

Because of the potential for their overlapping circumstances of exposure, diethyltoluamide (DEET) encephalopathy should be excluded. DEET-containing insect repellents have been implicated as a cause of seizures and encephalopathy after brief cutaneous exposure (see later discussion).

Valuable clues to the diagnosis of an arbovirus infection are gleaned from a history of travel, residence, or occupational and recreational activities within the appropriate incubation period. Suspected cases should be reported to public health officials.

TREATMENT

Specific US Food and Drug Administration–approved antiviral therapy is not available for WEE. However, novel small-molecule inhibitors of neurotropic alphaviruses, including WEE virus, are in preclinical development.^{47,56,68} Supportive treatment of acutely ill patients includes monitoring of cardiorespiratory function, fluid and electrolyte balance, and intracranial pressure. A case of laboratory infection treated with immune equine serum resulted in recovery; however, acute Parkinson syndrome developed in this patient and coincided temporally with serum sickness resulting from immunotherapy.²¹

PREVENTION

Killed vaccine prepared in chick embryo fibroblast culture is available in the United States under an investigatory permit for laboratory and field personnel who are at risk for occupational exposure. Effective killed vaccines are available for horses and usually are administered in bivalent or multivalent formulations (i.e., with EEE, Venezuelan equine encephalitis, and influenza viruses). Potential vaccine targets for WEE are under investigation and include E1 envelope protein targets and adenovirus vectored vaccines.^{72,79} Vaccination of the general public, even in endemic areas, is not a practical consideration because of the low risk for disease.

Personal protective measures are encouraged when travel or living in endemic areas, and include avoidance of outdoor activity during the hours of peak mosquito activity at dusk and use of repellents.

The Centers for Disease Control and Prevention (CDC) recommends repellents containing DEET or picaridin (KBR 3023) as active ingredients.^{10,11,19,25,51} DEET is absorbed readily through the skin, and its absorption and absorption of oxybenzone, a common sunscreen preparation, are increased when they are used in combination. Some authorities recommend that sunscreens be applied first and more liberally, followed by insect repellent applied sparingly because of concerns about the potential neurotoxicity of DEET.^{10,61,62} Three cases were fatal. In one recovered child, encephalopathy and seizures developed after only two applications. In an additional child, seizures and encephalopathy occurred after the child had cutaneous and respiratory exposure to DEET in an automobile with closed windows. Additional cases of seizures in patients who used small quantities of DEET have been reported, but whether these events were coincidental in populations in which the prevalence of DEET use is high is unclear.¹¹ DEET may have an effect on ammonia metabolism; in one case, encephalopathy occurred in a patient with partial ornithine carbamoyltransferase deficiency.²⁶ DEET is a proved neurotoxin when it is ingested; however, the incidence of neurologic side effects after cutaneous exposure is unknown. Nonetheless, avoiding formulations containing DEET in high concentration is prudent; when it is applied simultaneously with sunscreen, DEET repellency is unhampered but ultraviolet protection may be reduced. Precautions for the prudent use of repellents as recommended by the CDC and US Environmental Protection Agency (EPA) are listed in [Box 175B.1](#).

Repellents containing oil of lemon eucalyptus (but not “pure” oil of lemon eucalyptus) and registered with the EPA as repellents also may provide a similar level of protection.

BOX 175B.1 Precautions to Reduce Potential Adverse Reactions From Repellents

- DEET is approved for use on children older than 2 months. Read and follow label instructions.
- Repellents should be applied only to exposed skin and clothing (as directed on the product label). Do not use under clothing.
- Never use repellents over cuts, wounds, or irritated skin.
- Avoid mucosal contact—do not apply to the eyes and mouth, and apply sparingly around the ears. When using sprays, do not spray directly onto the face; spray on the hands first and then apply to the face.
- Do not allow children to handle the product, and do not apply to children's hands. When using on children, apply to your own hands and then put it on the child.
- Do not spray in enclosed areas. Avoid breathing a repellent spray.
- Avoid ingestion, and do not use the product near food.
- Use just enough repellent to cover exposed skin and clothing.
- Heavy application and saturation are unnecessary for effectiveness; if biting insects do not respond to a thin film of repellent, apply a bit more.
- After returning indoors, wash treated skin with soap and water or bathe. This precaution is particularly important when repellents are used repeatedly in a day or on consecutive days. Also, wash treated clothing before wearing it again.
- Pregnant and nursing women should minimize the use of repellents.
- If you suspect that you or your child is reacting to an insect repellent, discontinue use, wash treated skin, and then call your local poison control center. If you go to a physician, take the repellent with you.
- Specific medical information about the active ingredients in repellents and other pesticides is available at the National Pesticide Information Center at 800-858-7378.

Modified from US Environmental Protection Agency recommendations. Available at: <http://www.epa.gov/pesticides/factsheets/chemicals/deet/htm>.

Permethrin, a synthetic pyrethroid available as a 0.5% aerosol (Permanone), is both insecticidal and a repellent.^{11,19,64} Permethrin is extremely effective in reducing the incidence of mosquito and tick bites when sprayed on clothing and shoes, and it also can be applied to tents, mosquito nets, and other gear.^{19,63} Its use on the skin is not approved, except as treatment of scabies and head lice.

Prevention is focused primarily on interruption of the transmission of virus from mosquitoes to humans. In many localities where WEE is endemic, mosquito abatement districts monitor mosquito populations, virus infection rates in the vector population, or evidence of transmission of virus to wild or sentinel birds and chickens to provide a basis for predicting epidemic transmission and for emergency mosquito control.^{42,60}

As a general rule, *C. tarsalis* densities exceeding 10 to 15 females per trap night and mosquito infection rates greater than five to 10 per 1000 signal a risk for epizootic transmission. Evidence of seroconversion in sentinel chickens and observations of equine cases are further indications that human cases may occur.

175C ■ Venezuelan Equine Encephalitis

Gail J. Harrison • Theodore F. Tsai

Mosquito-borne Venezuelan equine encephalitis (VEE) arguably is the most important viral zoonosis in Latin America. The disease, known locally as *peste loca*, has occurred in combined epizootics and epidemics at regular intervals since the 1920s, sometimes leading to hundreds of thousands of human and equine cases. Between 1935 and 1961, 11 outbreaks were reported, and from 1962 to 1973, epizootics recurred in every year except 1965.^{1,4,20,44} The virus was isolated from horse brain in 1938 during an outbreak in Venezuela. Although outbreaks have arisen principally in northern South America, especially from Colombia and Venezuela, in a remarkable period between 1969 and 1971, epizootics and epidemics were reported from Colombia, Venezuela, Ecuador, Peru, all the countries of Central America (except Panama), Mexico, and the state of Texas.^{1,4,14,30,44} Subsequently, no major epizootics or epidemics were recognized until a large outbreak emerged in Venezuela and Colombia in 1995.^{7,8,35,48} Molecular phylogenetic analyses performed in the wake of that outbreak suggested that epizootic strains arise spontaneously from sylvatic viral strains circulating silently in nature.^{3,6,25,48} VEE virus is classified as a Category B bioterrorism agent and a Biosafety Level 3 (BSL-3) agent, based on its ability to cause disease in humans, ease of production and stability, and potential for aerosol dissemination in the population.⁵¹

ETIOLOGIC AGENT

VEE virus is antigenically distinct from other alphaviruses in the Togaviridae family but is a complex of antigenically and ecologically distinct viral subtypes (Table 175C.1).^{33,39,45,47,50} Epizootic subtypes IAB

and IC are so named because they have been associated with major outbreaks in horses. Sylvatic viral subtypes circulate in silent cycles of rodent-mosquito or bird-mosquito transmission and in general do not cause encephalitis in equines. Both epizootic and sylvatic viral strains cause human illness. VEE virus is an enveloped virus with a nonsegmented, positive-sense RNA genome approximately 11 kilobases in length.

VEE virus is thought to have evolved about 1400 years ago from a now extinct ancestral alphavirus in one of two extant lineages of New World alphaviruses represented by eastern equine encephalomyelitis and VEE viruses.³³ Because epizootic VEE viral strains had never been isolated from nature except during epizootics, their reservoirs and the mechanisms by which they emerge to cause outbreaks had remained a puzzle. However, recent molecular phylogenetic analyses have found a close genetic relationship between the epizootic IC and the sylvatic ID strains, thus suggesting that these epizootic strains might arise spontaneously by mutation from naturally circulating ID virus.^{1,3,6,47} Other outbreaks have had an iatrogenic source from improperly inactivated equine vaccine.^{21,22,33,36,47,48}

Comparisons of the attenuated TC-83 vaccine strain of VEE virus and the epizootic IAB parent virus and mutations of virulent infectious clones have shown that changes associated with attenuation occur principally in genes encoding the E2 and E1 glycoproteins but also in the 5' nontranslated region.^{3,6,21,39} Attenuation is associated with reduced neuroinvasiveness (i.e., faster clearance from blood and lower viremia levels) and reduced neurovirulence (i.e., minimal histopathologic changes after intracerebral inoculation of horses).

TABLE 175C.1 Viruses in the Venezuelan Equine Encephalomyelitis Complex

Subtype	Variety	Pattern of Transmission	Location	Transmission Cycle
I	AB	Epizootic	South, Central, and North America	Various mosquitoes and biting insects: equines
	C	Epizootic	Northern South America	Various mosquitoes and biting insects: equines
	D	Enzootic	Ecuador, Panama, Colombia, and Venezuela	<i>Culex (Melanoconion) ocosia</i> and <i>panocossa</i> : rodents, aquatic birds
	E	Enzootic	Central America	<i>Culex (Melanoconion) taeniopus</i> : rodents
	F	Enzootic	Brazil	Unknown
II (Everglades)		Enzootic	Southern Florida	<i>Culex (Melanoconion) cedecei</i> : rodents
III	A (Mucambo)	Enzootic	South America	<i>Culex (Melanoconion) portesi</i> : rodents
	B (Tonate)	Enzootic	South America	Unknown
	Bijou Bridge	Unknown	Western North America	<i>Oeciocacus vicarius</i> : birds
	C	Enzootic	Peru	Unknown
	D	Enzootic	Peru	<i>Culex (Melanoconion) Proechimys</i> spp.
IV (Pixuna)		Enzootic	Brazil	Unknown
V (Cabassou)		Enzootic	French Guiana	Unknown
VI		Enzootic	Argentina	Unknown

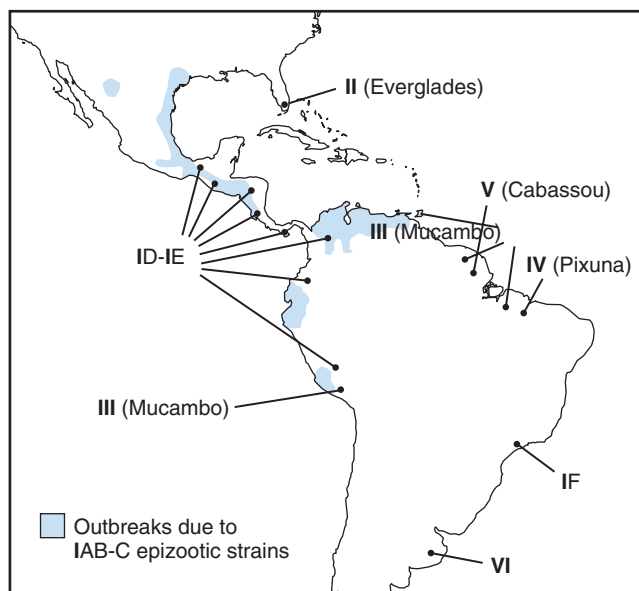

FIG. 175C.1 Locations of Venezuelan equine encephalitis (VEE) outbreaks caused by types IAB and IC epizootic strains and locations where VEE sylvatic subtypes have been recognized.

VEE virus rapidly produces cytopathic effects in a variety of cell cultures, including Vero, LLC-MK2, and BHK-21, and in primary chicken and duck embryo cells. Epizootic strains cause lethal infections in horses, donkeys, mules, rabbits, and dogs. In certain guinea pig strains, pathogenicity is correlated with equine virulence.

EPIDEMIOLOGY AND ECOLOGY

Epizootics and concurrent epidemics of VEE caused by the IAB and IC strains typically have led to thousands and, on at least one occasion, hundreds of thousands of cases in humans and equines. Surveillance for these mosquito-transmitted viruses are performed by public health laboratories using multiplex, reverse transcriptase polymerase chain reaction (RT-PCR), which can now detect multiple encephalomyelitis viruses in one reaction.⁴⁶ Most such outbreaks have occurred in Venezuela and Colombia and have been caused by IC viruses (see earlier discussion) (Fig. 175C.1).^{35,38,47,48} The circumstances leading to the emergence of outbreaks are poorly understood, but outbreaks often have occurred in arid areas during years of heavy rainfall and flooding, especially during the dry season.⁴⁴ The importance of a nonimmune horse

population to amplify the virus was underscored in the most recent outbreak in 1995, which occurred in areas of Colombia and Venezuela where equine immunizations had lapsed.^{7,35,48} Equines are the most important vertebrate amplifying host because high levels of viremia develop and are sustained in equines, and they provide a large surface area for biting mosquitoes. Numerous species of mosquitoes and other blood-feeding insects, among them *Aedes taeniorhynchus*, a salt marsh mosquito, and *Psorophora confinnis*, found in ground pools, can transmit the virus from horse to horse and from horse to human.⁴¹

Infections are transmitted rapidly among animals and to people such that outbreaks can disseminate at rates of several miles per day. The epidemic curve of human cases usually follows the equine epizootic by several weeks, and epidemic transmission ceases when the number of susceptible horses has been exhausted by immunization or natural infection.^{17,44}

The role of other animals, including humans, in sustaining epidemic viral transmission has been investigated in urban outbreaks, during which household clustering of cases has been observed, and in recent outbreaks, during which few horses were kept in the community. VEE virus levels in human blood are sufficiently high to infect mosquitoes, and virus also has been isolated from the pharynx of ill persons, indicating the possibility of person-to-person transmission by mosquitoes such as *Aedes aegypti* or by direct close contact.^{3,40} Although such transmission mechanisms may account for some cases, a household survey found that rates of apparent secondary transmission were no higher than the underlying community attack rate.^{7,35} Community attack rates of 20% to 50% have been recorded, and the brief course of epidemics in intervals as short as 1 month underscores the considerable force of epidemic transmission.

The series of epizootics beginning in Guatemala in 1969 and reaching Texas in 1971 was caused by an IAB virus that is almost genetically identical to the 1943 Trinidad donkey (epizootic IAB) virus used in inactivated vaccines, thus leading to the conclusion that these outbreaks were iatrogenic and caused by the use of inadequately inactivated equine vaccine.^{4,22,47} Another outbreak in Argentina was traced to a similar cause. Serologic serosurveillance in the Gulf Coast region of Mexico conducted between 2003 and 2010 showed that the Gulf Coast lineage of VEE virus continues to actively circulate and be responsible for infection of animals and humans in this region.³⁵

In contrast to the epizootic strains, sylvatic VEE viruses are avirulent in horses and cause a low level of viremia after infection, subclinical or mild illness, and minimal inflammatory change after direct intracerebral inoculation.⁴³ However, outbreaks of enzootic IE-like viruses rarely have caused outbreaks and deaths in horses (e.g., in Chiapas, Mexico, in 1993). The viruses are maintained in mosquitoes—principally *Culex (Melanoconion) taeniopus* in marshy coastal lowlands, in rodents—and in aquatic birds. In coastal lagoons in Panama, white ibises (*Endocinthus albus*) and boat-billed heron (*Cochlearius cochlearius*) appear to serve

as intermediate hosts.² VEE subtype II virus, the Everglades virus, is enzootic among cotton rats and other small mammals in the Everglades swamp and probably over a much larger area of Florida but rarely has caused human illness.^{9,12} The other VEE virus found in the United States, Bijou Bridge virus, is a nonpathogenic virus thought to have evolved from South American subtype III virus transferred as recently as 40 years ago, probably by a migrating bird.

VEE infections caused by sylvatic strains can be considered “diseases of place” that occur sporadically in persons who enter sylvatic habitats where the viruses are maintained.^{2,9} Sporadic cases and rare outbreaks among soldiers in field bivouacs have been reported, but seroprevalence rates in local populations range as high as 75% in some locations (e.g., Chiapas, Mexico).^{18,37} Many infections are undoubtedly undiagnosed. Bridge vectors, mosquitoes that feed on mammals in the enzootic transmission cycle and subsequently on humans, usually are responsible for these infections.

Numerous cases and outbreaks of VEE have occurred in laboratories when infective aerosols were generated in laboratory procedures.²³ It also has been developed as a biologic weapon in the United States and the former Soviet Union.⁵¹ Laboratory manipulations should be undertaken only in BL-3 laboratories and by immunized personnel.

Travelers to Central or South America may return to nonendemic areas with signs and symptoms of VEE. Careful travel history is therefore important in patients who seek medical care with signs and symptoms of encephalitis.²⁷

CLINICAL MANIFESTATIONS

The incubation period is brief—2 to 5 days—and in many accounts, the onset of illness was so sudden that it was timed to an exact hour.²³ Fever, chills, headache, myalgia, and malaise are the earliest symptoms, and illness quickly leads to prostration. Photophobia, neck stiffness, backache, conjunctivitis, and sore throat are also common symptoms that occur in approximately one-fourth or more of cases. Gastrointestinal complaints, especially nausea and vomiting, and, to a lesser degree, loose stools or diarrhea, are reported frequently.⁵ The case-fatality rate of VEE is estimated at 1%, but approximately 15% of survivors may experience severe neurologic sequelae. Asymptomatic infections also occur.

Physical examination discloses severe prostration and few specific findings. The face may appear hyperemic; inflammation of the pharynx is common; and, occasionally, tonsillitis, palatal ulcers, or petechiae are observed. The cervical lymph nodes may be enlarged and tender. Conjunctivitis and conjunctival suffusion are noted frequently. Nuchal rigidity can be elicited in 10% of cases, more often in children. Despite the disease's name, the symptoms of confusion, agitation, and mild disturbances in consciousness suggesting encephalitis are present in only 5% to 10% of cases, and patients with significant neurologic findings, such as cranial nerve palsy, motor weakness and paralysis, seizures, and coma, usually account for fewer than 5% of all cases.^{5,35,36} In epidemics, neurologic findings and encephalitis occurred more commonly in children; however, sporadic cases, including encephalitis caused by VEE subtype II (Everglades) and III (Tonate) viruses, have occurred in middle-aged or elderly adults.^{12,18} The fatality rate among patients with encephalitis is 10% to 25%, or about 0.5% of all cases.^{35,36}

In many patients, the illness has an apparently biphasic course; seizures, projectile vomiting, and ataxia occur several days after the onset of fever, followed rapidly by a complete resolution of symptoms. Sequelae such as nervousness, forgetfulness, recurrent headache, and easy fatigability are common occurrences and may persist for months or even up to 1 year. Motor abnormalities usually resolve without residual deficit; however, rarely, sensory and motor abnormalities may persist. Long-term effects on psychometric examination have been reported.²⁴

Experimental observations in animals suggest that congenital infection may lead to central nervous system (CNS) anomalies such as porencephaly, microcephaly, and hydrocephalus.²⁵ A similar pattern of structural brain abnormalities has been observed in virus culture–positive fetuses aborted during outbreaks.^{48,49} Pancreatic β -cell infection occurs in experimentally infected animals and has led to speculation that VEE

may be followed by diabetes, but epidemiologic studies have failed to find an association.²⁴

The principal clinical laboratory finding is leukopenia ($<4500/\text{mm}^3$), the nadir of which occurs on the fourth day of illness.^{5,11} After the onset of illness, the absolute neutrophil count declines from normal values to 500 to 2000; total lymphocytes are depressed at the onset of illness and gradually recover after 1 week. The platelet count may be diminished below $100,000/\text{mm}^3$, and lactate dehydrogenase and hepatic transaminases may be elevated moderately. Cerebrospinal fluid (CSF) shows a lymphocytic pleocytosis of up to several hundred cells, moderately elevated protein level, and normal or slightly depressed glucose concentration.

PATHOLOGY AND PATHOGENESIS

VEE virus is both lymphotropic and neurotropic.^{10,42} Pathologic changes are observed consistently in the lymph nodes, spleen, lungs, liver, gastrointestinal lymphoid tissue, and brain, with inflammatory infiltrates of mononuclear and polymorphonuclear cells. The lymph nodes and spleen show pronounced lymphoid depletion and necrosis of the germinal centers, along with neutrophilic infiltration and lymphophagocytosis. The selective depletion of lymphoid follicles, with sparing of the paracortical areas and the thymus, suggests that VEE virus principally destroys B cells. These histopathologic changes are reflected in the early lymphopenia seen in the peripheral blood. The liver shows patchy hepatocellular degeneration typical of viral hepatitis. A diffuse interstitial pneumonia with a mixed intraseptal inflammatory cell infiltrate is a consistent finding, and some cases also exhibit intraalveolar hemorrhage, secondary bronchopneumonia, or both. The brain shows only congestion and edema in most cases. Mild, often focal meningitis and changes associated with encephalitis, perivascular inflammatory infiltrates, and neuronal degeneration are found in a large number of cases.¹⁰ The consistent presence of congestion and edema in various organs and the necrotizing vasculitis seen in some cases suggest that vascular endothelial cells may be a target of infection. This speculation is supported by the observation of VEE viral antigen in the vascular endothelial cells of experimentally infected animals. Secondary immune-mediated destruction of infected vascular endothelia and lymphoid cells may account for delayed clinical manifestations.

LABORATORY DIAGNOSIS

VEE virus can be recovered and grown in cell culture from blood during the first 3 days of illness in at least 75% of cases, although isolates have been made after 6 days.^{3,4} Virus also has been recovered from throat swabs in approximately 25% of cases.²⁴ Specimens should be inoculated onto Vero or other susceptible cell cultures, but only in a laboratory with BL-3 level containment because of the risk for laboratory aerosol-associated infection. Virus in samples collected and transported in commercial transport media may not support the growth of VEE but will preserve the nucleic acid and protein integrity of the virus.¹⁹ As an alternative to viral isolation, genomic sequences in acute viremic blood and other samples can be detected rapidly and with high sensitivity by PCR in reference laboratories and genotyped using nested RT-PCR assay.³¹ Establishing the subtype of VEE viral isolates is vital because subtypes IAB and IC have a potential for epidemic spread. Isolates can be identified rapidly with subtype-specific monoclonal antibodies.

Immunoglobulin M (IgM) capture enzyme-linked immunosorbent assay is the recommended serologic procedure. Both serum and CSF specimens can be tested by this means. Elevated virus-specific IgM in a single serum or CSF specimen is diagnostic and often obviates the need for a second paired serum. An epitope-blocking assay can differentiate antibody responses among serotypes.⁴⁵

DIFFERENTIAL DIAGNOSIS

The self-limited acute febrile illness that characterizes most VEE cases resembles infection caused by dengue, Oropouche, Mayaro, group C bunyaviruses, and various other arboviruses. The epidemic occurrence of cases may suggest dengue or Oropouche fever; however, the absence of rash and hemorrhagic manifestations and an association with equine

deaths strongly indicate VEE until it is disproved. Eastern and western equine encephalitis infections overlap with VEE in some areas of Latin America, but only sporadic human cases have been recognized. Clinical recognition of sporadic VEE caused by sylvatic viruses is difficult; the diagnosis should be entertained in patients with CNS infection and an appropriate exposure history.

TREATMENT

No specific US Food and Drug Administration–approved antiviral treatment is available for VEE. Symptomatic treatment with antipyretics and fluids alone is sufficient in most cases. In patients with encephalitis, anticonvulsants may be needed, and intensive supportive care, especially early recognition and treatment of secondary pneumonia, may improve the outcome. Combinations of short interfering RNAs and passive immunization with humanized monoclonal antibodies are under preclinical development and investigation as therapeutic interventions.^{16,28,34}

Development of VEE antibody preparations from human transchromosomal cows, a new therapeutic platform, may eventually reach clinical trials in humans.¹⁵

PREVENTION

Immunization with experimental live attenuated TC-83 vaccine is indicated for laboratory and field personnel with a high risk for exposure to VEE virus.³² However, the vaccine is immunogenic in only 85% of vaccinees, and significant side effects consisting of fever, stiff neck, malaise, and myalgia develop in approximately 20% of vaccinees.¹³ Previous vaccination with alphaviral vaccines may interfere with response to TC-83, but after immunization with experimental inactivated TC-84 vaccine, antibody will develop in approximately 75% of persons who failed to respond to TC-83.^{13,26} Safer candidate vaccines that may provide better protection against respiratory infection are being investigated.

Immunization of equines with TC-83 vaccine is the best approach to preventing the emergence of outbreaks. Inadequately inactivated vaccine prepared from epizootic IAB strains poses a danger of producing iatrogenic outbreaks and should be used only if appropriate safety and quality assurance standards of vaccine production have been met. The original TC-83 vaccine virus also may be transmitted by mosquito vectors, and efforts have been made to improve its safety by preventing its ability to infect insects; this was done through manipulation of structural protein gene expression to produce further attenuation and render the vaccine virus incapable of replicating in insects.²⁹ Because the live vaccine provides rapid immunity after a single dose, it is the most effective approach in combating outbreaks. Attenuated vaccine is available commercially in certain Latin American countries, but in the United States, only inactivated vaccine formulated with western and eastern equine encephalitis and equine influenza and tetanus antigens is licensed. An improved candidate vaccine, V3526, has been shown to be efficacious in horses.¹³ Preclinical development of new, novel VEE vaccines includes Sindbis virus and VEE chimeric viruses, alphavirus replicon particles, DNA vaccines, and adenovirus vector vaccines.²⁹

Mosquito control with a combination of larvicides and adulticides may be indicated to mitigate large outbreaks. Taking precautions against mosquito bites, such as using repellents, staying in well-screened or air-conditioned areas when possible, and wearing long-sleeved shirts and long pants, is advised for persons who cannot avoid traveling to areas experiencing epidemics.

175D ■ Chikungunya

Scott B. Halstead

Chikungunya is a benign short-duration dengue-like febrile syndrome in children that in the very young carries a high risk for complicated outcomes. Infections of neonates may result in an elevated risk for neurologic complications and in a pantropic disease with a significant fatality rate. In adults, chikungunya produces fever followed by leukopenia, maculopapular rash, and arthralgia that may persist for months as polyarthritides. In the Makonde language *chikungunya* means “that which bends up,” referring to the characteristic symptom of arthralgia.⁸⁰ In historical times, the terms *knokkel koorts*, *abu rokab*, *mal de genoux*, *dengue*, *dyenga*, and *3-day fever* have been given to epidemics probably caused by chikungunya virus.^{14,35}

ETIOLOGIC AGENT

Chikungunya virus was isolated in 1952 by inoculating suckling mice with infected mosquitoes and blood from cases during an explosive dengue-like epidemic in the Makonde district on the border between Tanganyika and Mozambique.^{52,59,80,82} Chikungunya genome consists of a capped 11.8-kilobase positive-sense single-stranded RNA with a poly(A) tail. The genome is composed of two open reading frames (ORFs) between nontranslated regions. The ORF located at the 5′ end of the genome encodes a polyprotein precursor of nonstructural proteins with replicative and proteolytic activities. The second ORF encodes the polyprotein precursor of the structural proteins.⁷⁰

Chikungunya virus is an alphavirus in the Togavirus family and a member of the Semliki Forest complex related to Ross River, o’nyong-nyong, and Semliki Forest viruses.⁷⁰ Phylogenetic analysis of the E1

envelope glycoprotein divides chikungunya virus into two distinct geographic genotypes.^{71,101} One genotype consists of viruses from Senegal and Nigeria and is named the *West Africa genotype*. These viruses have only 78% to 85% nucleotide sequence identity to viruses of East, Central, and South Africa (ECSA) and the closely related Asian viruses. The phyletic grouping is consistent with the introduction during 1879 to 1956 of East African strains into Asia, where it continues to circulate.^{71,101}

Chikungunya virus produces death in infant mice, rats, and hamsters after intracerebral inoculation. Serial passage of the virus in mice has resulted in selection of a strain with a short incubation period that is lethal to weanling mice.⁸² Virus grows to titers of 10⁸ to 10⁹ infectious doses per milliliter. Low-passage material is highly infectious for humans during routine laboratory handling, and therefore appropriate precautions should be taken by laboratory workers. If a mouse brain seed suspension of low-passage virus is prepared and inoculated into other mice at a 1:5 or 1:10 final concentration, death may be delayed significantly, may be sporadic, or may not occur at all. This difference is due to autointerference caused by an Asian strain that also produced hemorrhagic enteritis in rats and hamsters.³⁶

Chikungunya virus produces a cytopathic effect in primary hamster kidney cells and in BHK-21, BSC-1, Vero, FL, HeLa, and rhesus kidney cells.⁴⁵ Virus multiplies in *Aedes albopictus*, *Aedes aegypti*, *Aedes vittatus*, *Anopheles stephensi*, and *Culex fatigans* continuous cell lines and in a cell line derived from *Drosophila*. Plaque assays have been described in LLC-MK2, Vero, and BHK-21 cells and in duck and chick embryo cell cultures.⁴⁵

ZOONOTIC CYCLES

Chikungunya virus has been recovered from wild *A. aegypti* in Tanzania, Nigeria, India, and Thailand; from *Aedes africanus* in Uganda and Bangui; from *Aedes furcifer-taylori* in South Africa and Senegal; and from *Aedes luteocephalus* and *Aedes dalzieli* in Senegal.^{3,20,26,44,59,61} Occasional isolates have been recovered from *Mansonia fuscopennata* in Uganda and from *C. fatigans* in Thailand and Tanzania. Transmission to humans has been demonstrated with the *A. furcifer-taylori* group; transmission to monkeys or mice has been demonstrated with *A. aegypti*, *A. albopictus*, *Aedes calceatus*, *Aedes triseriatus*, *Aedes togoi*, *Aedes pseudoscutellaris*, *Aedes polynesiensis*, *Anopheles albinus*, *Mansonia africana*, and *Aedes apicoargenteus*.^{45,57,67,87}

Chikungunya antibodies have been found in vervet monkeys, baboons, chimpanzees, and red-tailed monkeys in Zimbabwe, South Africa, and Uganda.⁵⁶ In Africa, zoonotic transmission to subhuman primates is surmised to take place in a wide variety of habitats, with transmission occurring in the forest canopy, at ground level, or both.⁵⁸ Chikungunya appears to be enzootic throughout much of eastern, central, southern, and western Africa.⁴⁵ Subhuman primate populations are affected in epizootics, which involve critical numbers of the susceptible population, followed by disappearance of the virus. Thus chikungunya may maintain itself in wildlife populations by constantly moving epizootic activity, in much the same fashion as respiratory tract and enteric virus infections are maintained in humans. A series of outbreaks originating from Central-South African lineage strains caused outbreaks in Cameroon and Gabon in 2007.⁹⁸

Based on human outbreaks, chikungunya virus has emerged to cause Asian pandemics from its East African zoonotic cycle at roughly 50-year intervals since 1770. The factors that control this phenomenon are unidentified.

EPIDEMIOLOGY

History

The classical account, widely thought to be the initial description of “dengue fever,” is a report by David Bylon, who was *staads chirurgyn* (“city surgeon”) to the Batavia (capital of the Dutch East Indies, now Jakarta) in the year 1779.¹² Dr. Bylon, who himself contracted the illness, wrote the following:

It was last May 25, in the afternoon at 5:00 when I noted while talking with two good friends of mine, a growing pain in my right hand, and the joints of the lower arm, which step by step proceeded upward to the shoulder and then continued onto all my limbs; so much so that at 9:00 that same evening I was already in my bed with a high fever...

It's now been three weeks since I ... was stricken by the illness, and because of that had to stay home for 5 days; but even until today I have continuously pain and stiffness in the joints of both feet, with swelling of both ankles; so much so, that when I get up in the morning, or have sat up for a while and start to move again, I cannot do so very well and going up and down stairs is very painful.

This account of a febrile illness of acute onset with prominent involvement of the joints clearly suggests that this was chikungunya (see [Clinical Manifestations](#)). In the same year in Cairo and Alexandria, Egypt, a large outbreak occurred of a disease with these same features.^{14,18,19,88} An important pandemic of a febrile exanthem occurred in the years 1870 to 1873 appearing first on the East African coast and then on the coasts of Arabia, Port Said, and Egypt. From there it was carried to Bombay and Calcutta, India, and Java. The 1870 outbreak led to the recognition that the Swahili words for this disease were *ki-dinga pepo*.¹⁸ The term *denga* or *dyenga* had been used to designate this same disease in Africa during an earlier outbreak in 1823. In that pandemic, *denga* had spread with the slave trade to the Caribbean, where in 1827 the virus was introduced on St. Thomas then throughout the Caribbean and the Atlantic coastal cities of North and South America.^{19,35} In Cuba, the Spanish homonym of *dyenga*, *dengue*, was introduced.

In 2005–06 a notable epidemic occurred on Reunion, Mauritius, Madagascar, Mayotte, and Seychelles.⁷⁶ This soon spread to India and to Southeast Asia.^{48,73} The Reunion virus was brought by tourists to Europe, where modest autochthonous outbreaks occurred in southeastern

France and northeastern Italy.^{33,69} In 2013, the older ECSA-Asian genotype virus reached the American hemisphere after an absence of almost 200 years. As in 1827, chikungunya was first identified on an island adjacent to St. Thomas. As of April 2016, the Pan American Health Organization had reported that autochthonous transmission of the disease, first recognized in December 2013, was reported from 52 countries or territories in the Caribbean and Central, South, and North America. A total of 1,851,157 suspected and 65,066 laboratory-confirmed cases and 211 deaths had been attributed to chikungunya. During 2017, more than 150,000 cases and 88 deaths from suspected or confirmed chikungunya were reported to the Pan American Health Organization as of September 17, 2017.¹⁰⁴ Chikungunya virus completed the circumnavigation of the globe when Caribbean virus was introduced into Europe and Africa.²⁵

Geographic Distribution

When susceptible human and *A. aegypti* or *A. albopictus* populations are above the threshold level required for chikungunya transmission, a person-mosquito-person cycle is established. This cycle probably is responsible for most of the large urban outbreaks of chikungunya studied during the past 40 years. Characteristically, chikungunya pandemics transmitted by *A. aegypti* are explosive. Studying *A. aegypti* in laboratory mice, Rao and colleagues documented mechanical transmission.⁷⁵ Viremia in humans may be as high as 10⁸ infectious doses per milliliter.⁷⁵ Because the extrinsic incubation period in *A. aegypti* is relatively long, the explosive nature of chikungunya outbreaks was thought to be best explained by mechanical transmission, possibly complemented by biting *Culex* species. During the introduction of chikungunya on Reunion in 2005, an amino acid substitution in position 224 of the E1 protein resulted in enhanced transmissibility by *A. albopictus*. Subsequently, a further mutation occurred in E2-L210Q that enhanced fitness in *A. albopictus*. The new ECSA variants produced the huge Asian pandemic that followed the Reunion outbreak.^{99,100} On Reunion the *A. albopictus*-borne outbreak, with a duration of about 4 months, affected an estimated 35% of a population of 800,000.⁷⁷ Ironically, it was the older ECSA-Asian strain that, when introduced into the Americas in 2013, produced the hemispheric pandemic.¹⁰³

Serologic studies have demonstrated repeatedly the presence of antibodies in humans throughout the moist forests and semiarid savannas of East and West Africa.^{1,26,61,84} In Africa, chikungunya outbreaks have been reported from Uganda, Tanzania, Zimbabwe, South Africa, Angola, Zaire, Nigeria, Senegal, Madagascar, and Reunion.⁴⁵ This distribution best fits the present location of virus research laboratories. A reasonable assumption is that chikungunya is endemic throughout sub-Saharan Africa. According to historical reports, pandemics swept into India in 1824, 1871, 1902, 1923, and during the modern virologic era in 1963 and 2006, extending into the Indonesian archipelago in the 18th and 19th centuries.^{14,19,88}

At some point in time, the ECSA chikungunya virus became established in South East Asia. An extensive neutralizing antibody survey suggested chikungunya activity during World War II in Kalimantan and Sulawesi, Indonesia.⁹¹ In the late 1950s and early 1960s, chikungunya was found to be transmitted continuously in urban and rural Thailand, Cambodia, and South Vietnam.^{16,38,39,102} Involvement of urban populations in Burma appears to have been intermittent, with outbreaks recorded in 1963 and from 1970 to 1973.⁶⁰ A large chikungunya epidemic affected much of Indonesia in 1983 and 1984 and Burma in 1984 and 1985.⁹⁴ Chikungunya virus was isolated in Australia in 1989.⁴⁰ Serologic evidence of chikungunya virus infection has been found throughout the Philippines, possibly during World War II. Since then, localized outbreaks have occurred in Manila, Philippines, in 1967 and Negros, Philippines, in 1968,^{5,13,53,85} and as recently as 2012–13.⁸⁵ After having disappeared in the 1970s, chikungunya was found again at low-level transmission in Thailand, Myanmar (formerly Burma), and Indonesia in 1990.⁹³ Little or no chikungunya virus activity was reported in the 20th century in Papua New Guinea, the Solomon Islands, Vanuatu (formerly New Hebrides), the Caroline Islands, the Pacific Islands, or any of the American tropics.⁹²

A pertinent question to ask is why chikungunya and dengue viruses, both transmitted by *A. aegypti*, do not have an identical geographic distribution. This may be due partially to differences in the

transmissibility of chikungunya and dengue by vector mosquitoes. The threshold for infection of chikungunya virus in *A. aegypti* is relatively high, approximately 10^6 mouse infectious doses are required to infect 50% of adult female mosquitoes.⁹² The infection threshold of female *A. aegypti* for dengue virus is rather similar. However, *A. aegypti* mosquitoes infected with chikungunya virus transmit virus to vertebrates poorly, whereas dengue-infected mosquitoes transmit with great regularity.³⁴ Thus transmission of chikungunya virus is expected in areas with high human susceptibility rates and high densities of *A. aegypti*.

CLINICAL MANIFESTATIONS

The global pandemic of chikungunya that followed the escape of virus from East Africa in 2005 has added substantially to our understanding of the clinical and pathophysiologic attributes of human infection. Infections in young children are predominantly inapparent.⁴ The incubation period of chikungunya fever is usually 2 to 4 days. In infants, the disease typically begins with the abrupt onset of fever, followed by flushing of the skin. Febrile convulsions may occur in as many as one-third of patients. After 3 to 5 days of fever, a generalized maculopapular rash and lymphadenopathy are noted. Conjunctival injection, swelling of the eyelids, pharyngitis, and signs and symptoms of upper respiratory tract disease are common. No enanthem occurs. Some infants have a biphasic fever curve, and arthralgia may be quite severe, although it is not seen frequently. In Nicaragua, 2.9% of children older than 9 years had arthritis.^{4,9,15,37,43,65}

Chikungunya infections early in pregnancy may infect the fetus rarely and result in a miscarriage.³⁰ Vertical transmission is rare. Of 678 women with antepartum or peripartum chikungunya who delivered live babies, none circulated chikungunya immunoglobulin M (IgM) antibodies. Perinatal infections of neonates were reported on Reunion, rising to nearly 50% when mothers were viremic in the week just preceding delivery.⁷⁴ Of 39 babies born to mothers experiencing chikungunya infections at the time of delivery, all developed a febrile illness beginning on day 4. Caesarean delivery of infants did not prevent chikungunya infections. Nine of these infants developed encephalopathy. Lymphopenia and thrombocytopenia were common, in some cases profound, but without severe bleeding. Most infants with chikungunya infections developed erythematous skin lesions and evidence of joint involvement. During the chikungunya outbreak on Reunion, 25% of young children developed neurologic symptoms, whereas in India 14% of all children presenting with suspected central nervous system infection had chikungunya.^{51,78} Sequelae were studied in 35 Reunion babies infected perinatally. At 21 months, infected children exhibit poorer neurocognitive skills than uninfected peers as evidenced by lower global developmental

quotient scores and diminished specific neurocognitive skills, even reaching abnormal ranges for coordination and language. The incidence of the global developmental delay in infected children was just more than 50%.³² Rarely, infants younger than 6 months with chikungunya may exhibit extensive bullous skin lesions with blistering covering up to 35% of the body surface area.⁷⁹

In older children, fever is accompanied by headache, myalgia, and arthralgia involving various joints. Residual arthralgia has been described but is uncommon.⁴¹ Joint pain is typically polyarticular, bilateral, and symmetric and affects mainly the extremities (ankles, wrists, phalanges) but also larger joints (shoulders, elbows, knees).^{55,89,95} Joint symptoms can fluctuate in intensity, but do not usually vary in their anatomic location. Swelling may also occur in the interphalangeal joints, wrists, and ankles, as well as pain along ligament insertions, notably in children. An early macular blush is followed by a maculopapular rash that accompanies or immediately precedes defervescence. At the same time, marked lymphadenopathy occurs. Febrile convulsions are observed commonly in younger children. Hemorrhagic findings, including a positive tourniquet test, are rare.^{9,15,37,43,65} Chikungunya viruses were recovered from saliva obtained during acute illness in 10 of 13 children, some of whom had bleeding gums.²⁹ As further evidence that chikungunya replicates in oral and nasal mucosa, three adult Venezuelan patients with virologically confirmed disease developed extensive acute nasal skin necrosis early in the course of a life-threatening illness characterized by shock and organ dysfunction.⁹⁷ There is evidence of direct person-to-person spread of chikungunya, presumably through infected mucosal secretions.⁸¹

Although dengue and chikungunya illnesses are similar, important distinguishing features are summarized in [Tables 175D.1 TO 175D.4](#) from clinical data obtained from children in Thailand.

[Table 175D.1](#) shows the abrupt onset and early severity of chikungunya versus dengue illnesses, many of which came to medical attention only several days after the onset of fever.

Chikungunya virus infections are shorter in duration than dengue virus infections (see [Table 175D.2](#)). Almost half of children with chikungunya had a fever that ended within 72 hours after onset, whereas the median duration of dengue fever was 2 days longer.

Many constitutional signs and symptoms occur with similar frequency in chikungunya and dengue viral infections and cannot be used to differentiate the illnesses clinically (see [Table 175D.3](#)). However, a terminal maculopapular rash, arthralgia or arthritis, and conjunctival injection were more common symptoms in chikungunya than in dengue (see [Table 175D.4](#)). Shock has been reported infrequently in chikungunya.^{15,86,96} It was not observed in Thai cases.⁶⁵ Changes in taste perception and bradycardia, depression, or asthenia after illness are found rarely in

significantly from that in chikungunya cases. However, petechial rash and spontaneous hematemesis or melena developed in only hospitalized dengue cases.

PATHOGENESIS AND PATHOLOGY

The pathophysiology of chikungunya chronic disease remains poorly understood, and to date, no animal model fully reproduces the chronic joint syndrome associated with many cases. In humans, patients with chronic chikungunya-induced arthralgia often have persistent virus-specific IgM that could result from continued exposure to chikungunya antigen.^{7,50,54} A C57BL/6J mouse model results in arthritis, tenosynovitis, and myositis.⁶² Chikungunya infection in nonhuman primates (NHPs) results in acute fever, rash, viremia, and production of interferon type 1. NHPs develop CHIKV-specific B and T cells, generating neutralizing antibodies and specific CD4⁺ and CD8⁺ T cells.¹¹ In a cynomolgus monkey model with long-duration chikungunya, spleen, liver, muscle, and joint infection have been described.⁴⁷ Chikungunya antigens have been detected by immunohistochemistry in muscle satellite cells of muscle biopsy specimens from two patients with a myositic syndrome⁶⁶ and in fibroblasts of the joint capsule, skeletal muscle, and dermis from a fatal neonatal case.^{22,23} Chikungunya virus infects and persists in human cornea tissue, and viral infection has been transmitted surgically.²¹ In vitro studies have shown that other cell types, such as human epithelial and endothelial cells, primary fibroblasts, and to a lesser extent, monocyte-derived macrophages, are also able to sustain productive chikungunya infections.^{22,23,47} Wild-type chikungunya strains produce a hemorrhagic enteritis in mice and hamsters.³⁶ NHPs are useful for

preclinical testing of vaccines and therapeutics and uncovering the details of pathogenesis.

DIAGNOSIS

The differential diagnosis includes the viral causes of dengue fever syndrome.⁴⁹ In Australia and the western Pacific area, Ross River fever is a frequent cause of epidemic, arthropod-borne, viral arthralgia.

Laboratory diagnosis depends on demonstrating chikungunya virus or viral RNA during the first 5 days after onset of fever or detection of IgM chikungunya antibodies 5 or more days after onset of fever.^{42,72} Commercially, these are detected using the IgM-capture enzyme-linked immunosorbent assay. The assays currently on the market perform well, although they are unable to distinguish chikungunya from viruses in the Semliki Forest virus group.^{6,46,64,72} Virus may be isolated by inoculating acute-phase serum or other suspect materials intracerebrally in 1- to 2-day-old mice or in tissue cultures. On initial passage, death may occur within 2 to 5 days after inoculation. An autointerference phenomenon is noted if low-dilution passages of infected mouse brain are performed. Passage at a 10⁻³ dilution or higher avoids this effect. Vero cells and suckling mice are equally effective for primary isolation. To differentiate infections caused by other members of the Semliki Forest viral group, neutralizing antibodies can be measured on convalescent sera.

TREATMENT

Treatment is supportive. Antirheumatoid drugs may be effective for management of chronic arthritis; however, chloroquine phosphate 250 mg/day, once touted for management of acute arthritic pain, had no effect in a double-blinded trial.²⁴ Analgesics or mild sedation may be required to control pain. Arthritis after illness may require continued treatment with antiinflammatory agents and graduated physiotherapy. Salicylates, because of their hemorrhagic potential, are contraindicated. Bed rest is advised during the febrile period. Antipyretics or cold sponging should be used to keep the body temperature below 40°C (104°F).

Seizures may be benign febrile seizures or may be a sign of encephalitis and may be treated with anticonvulsant medications. Children who have lost excessive fluid because of vomiting, fasting, or thirsting and who cannot take oral fluids may require intravenous rehydration. Individuals with severe hemorrhagic phenomena should be evaluated for underlying clotting disorders.

Human neutralizing monoclonal antibodies directed against E2 or E1 significantly delay lethality of chikungunya-infected mice, in both prophylactic and therapeutic settings.^{27,28} It has been suggested that administration of chikungunya antibodies might protect infants exposed to infection perinatally.^{22,23}

PROGNOSIS

In some instances, isolation or serologic evidence of recent infection has been obtained in persons with severe hemorrhagic findings and in individuals dying during an acute febrile illness.^{15,43,63,76,86} In addition to hemorrhage, neurologic and myocardial involvement has been reported during chikungunya infection in adults.^{15,17,22} In adults, arthralgia may persist for weeks, and exercise may prolong this symptom. Typically, pain shifts from joint to joint and is worse in the morning and on first use of the joint. Swelling of ankles, wrists, and fingers occurs frequently. In older patients, the sequelae may resemble rheumatoid arthritis.⁸ In the Reunion Island outbreak, 57% of adult patients experienced long-duration symptoms, half of which impaired daily activities.⁹⁰ Chronic rheumatic manifestations were associated with age, severity of initial acute illness pain, and presence of osteoarthritis.⁹⁰ A destructive arthropathy after illness has been reported.^{10,55} Chikungunya virus infection might coincide with other pathologic processes and result in death of the individual. Carefully studied, virologically documented cases have shown neither thrombocytopenia nor severe neutropenia.^{43,55} Until more is known of the pathogenesis of chikungunya virus infection, estimating the frequency with which death can be attributed directly to chikungunya fever will be difficult.

Infants with chikungunya may experience residual neurologic deficits after recovery from encephalitis.^{22,23,31}

PREVENTION

A very large number of chikungunya vaccine constructs have been developed and subjected to preclinical testing since the 1960s. These range from formalin inactivate whole virus and tissue culture passaged attenuated virus, to various chimeric, DNA, subunit and virus-like particle vaccines.² A measles chikungunya vaccine developed by the Institut Pasteur is projected to enter clinical trials by Themis Inc.² A vaccine engineered to carry an internal response sequence element between the nonstructural and the structural genes produced a successfully attenuated virus that prevented virus replication in vector mosquitoes. Further, in subhuman primates this vaccine was immunogenic and protective.^{68,83} Whether and when safe and protective chikungunya vaccines will come on to the market is an open question.

At present, prevention consists of avoiding mosquito bites. For urban outbreaks in most of the Asian and African tropics, the regimen for individual protection and for chronic and emergency control is the same as has been described for dengue. When other vectors are involved, measures designed to combat *A. aegypti* may fail. In such outbreaks, expert entomologic advice will be needed to design appropriate preventive measures.

175E ■ Ross River Virus Arthritis

John G. Aaskov • Roy A. Hall

Epidemics of a benign disease that caused polyarthralgia and rash were first described in Australia in 1927⁶⁹ and subsequently in 1943.⁴⁴ After recovery of the causative agent and the advent of serologic tests for diagnosing Ross River virus infection, epidemic polyarthritis was recognized as endemic in Australia. It has occurred as epidemics in numerous Pacific nations.

Approximately 4000 cases of epidemic polyarthritis are reported in Australia each year, with a peak of more than 9000 cases in 2015. In 2002, the median direct and indirect cost of a case of epidemic polyarthritis was estimated to be AUD\$2000. Approximately 50% of this amount resulted from disability and 30% from health care costs.⁷⁵

Some confusion has been generated by use of the term *Ross River fever* to describe clinical Ross River virus infections because fever does not develop in more than one half of those with clinical disease.⁶⁵ Additional confusion resulted from efforts to describe polyarthritis caused by any Australian arbovirus as epidemic polyarthritis. The term *epidemic polyarthritis* should be used to describe only clinical disease caused by Ross River virus.

ETIOLOGIC AGENT

Investigations of an epidemic of polyarthrititis in southern Australia in 1956^{14,83} suggested that an alphavirus was the causative agent. This was confirmed when Ross River virus was isolated from *Aedes vigilax* mosquitoes collected beside the Ross River near Townsville in northern Australia, and serologic evidence showed it to be the causative agent of epidemic polyarthrititis.^{26,29} Although the first isolation of virus from a human was from a febrile child without arthritis,²⁵ subsequent use of mosquito cell lines enabled Ross River virus to be recovered regularly from epidemic polyarthrititis patients.^{11,30,86}

Ross River virus is related serologically to Getah and Bebaru viruses in the Semliki Forest virus subgroup.²³ Nucleotide sequencing has confirmed the close relationship among Ross River, Getah, and Semliki

Forest viruses.⁷⁴ Phylogenetic analyses have identified four lineages of Ross River virus, three of which appear to have become extinct.⁵⁰ The appearance of the current lineage was associated with major genetic arrangements in the *nsP3* gene of Ross River virus.⁷ No association has been observed between any particular virus genotype and disease in humans, but this may be because most studies employ consensus nucleotide sequences for what, genetically, are very diverse viral populations.⁵⁹

Cryoelectron microscopic studies^{19,72,90} suggest that the nucleocapsid of Ross River virus is approximately 400 Å in diameter and has a triangulation (T) = 4 quaternary structure. It is surrounded by a membrane bilayer that is penetrated by 80 spikes that are also arranged in a T = 4 lattice. Each spike is a trimer of heterodimers of the envelope glycoproteins E1 and E2. The E2 protein makes contact with heparin on the surface of host cells, and antibodies that combine with this protein neutralize infection in vitro.^{5,84,87}

The virus can be adapted to grow to high titer in the muscle and brain of 1-day-old mice, in which it causes paralysis and death.^{62,66} Ross River virus also grows to high titer in vertebrate and mosquito cell lines.¹¹

TRANSMISSION AND EPIDEMIOLOGY

Ross River virus is endemic in all mainland states of Australia and in Papua New Guinea. The incidence of epidemic polyarthrititis is highest in the Australian states of Queensland, Northern Territory, and Western Australia, with other states experiencing outbreaks of infection against a background of low incidence (<http://www.health.gov.au/internet/main/publishing.nsf/Content/cda-surveil-nndss-nndssintro.htm>).

No transmission of Ross River virus had been reported from the Pacific island states involved in the 1979 to 1980 epidemic (Fiji, Samoa, Tonga, and Cook Islands)^{8,30,54,76,86} until 2003, when cases of epidemic polyarthrititis began to be detected in travelers who had visited Fiji,^{55,56}

suggesting that Ross River virus may have become endemic in that country. Sporadic cases without local virus transmission have occurred in Europe, the United States and countries in Southeast Asia that included tourists and military personnel returning from Australia.

Isolation of Ross River virus from more than 20 species of mosquitoes,⁷⁷ particularly *A. vigilax*^{29,42} and *Culex annulirostris*,^{28,42} and the presence of antibody to the virus in almost as many species of animals, particularly mammals,^{26,27,73} suggested a mammal-mosquito cycle with humans as an incidental host. However, improved laboratory diagnostic services have shown that clinical infection in humans occurs throughout the year, although most cases are seen in the late summer and in autumn, and most patients are city dwellers.^{10,65} Taken together with the explosive spread of disease during the 1979 to 1980 epidemic of Ross River virus infection in the Pacific,^{8,30,76,86} this virus appears to be maintained in either of two cycles, mammal-mosquito-mammal or human-mosquito-human, with movement of virus between the two. Evidence also has been obtained of transovarial transmission of Ross River virus in *Aedes* mosquitoes.^{53,58}

Patients may be viremic for up to 7 days after the onset of symptoms.^{10,76} The incubation time from infection to the onset of symptoms may vary from 1 to 27 days; an interval of 7 to 9 days is usual endemic areas.³⁵

In endemic areas, the ratio of subclinical to clinical infection may be as high as 50:1,¹⁰ but during outbreaks, the ratio can be reduced to 4:1 or less.^{8,45} Approximately 1.5% of humans living in northern Australia are infected with Ross River virus each year,¹⁰ but the rates are much higher in some areas.^{21,22}

Infection rates are the same for both sexes, and early reports that clinical disease was more common in females than in males^{24,65} are not supported by Australian national data for the past decade. An association between human leukocyte antigen DR7 (HLA-DR7) and clinical disease also has been observed.⁴¹

Ross River virus crosses the placenta in mice⁴ and humans.⁹ In mice, the result is extensive postpartum mortality,⁴ but in humans, no evidence of morbidity or mortality for children infected in utero has been found.

Although there was evidence of subclinical infection in blood donors² and the risk of transmission in blood transfusions had been identified,⁸⁸ the first recorded transmission of Ross River virus in a blood donation occurred in 2014, prompting the risk of transfusion-transmitted Ross River virus infection to be reevaluated in 2016.^{49,81}

CLINICAL MANIFESTATIONS

Epidemic polyarthritides occurs as a mild to severe illness characterized by joint pain, particularly in the knees and the small joints of the hands and feet. Frequently, the joint pain is accompanied by a maculopapular or vesicular rash on the trunk and limbs and sometimes by fever or chills, or both. Sore throat, lymphadenopathy, paresthesia, tenderness of the palms and soles, exanthems, and petechiae (rare) have been observed. Most patients experience several weeks of painful arthritis followed by a slow decrease in the severity of symptoms during the 30 to 40 weeks required by most for recovery.^{3,67} Infrequently, symptoms may persist for a year or more,³³ and some patients may experience episodes of severe arthritis during convalescence. One study linked Ross River virus infection to a chronic fatigue syndrome.⁴⁸

In less than 0.1% patients, clinical disease may develop without arthritis.²⁵ Rare cases of glomerulonephritis,³⁸ hematuria,¹⁵ and central nervous system symptoms^{1,60,71,78} accompanying Ross River virus infection in humans have been reported.

The severity and duration of symptoms are age related. Most clinical disease occurs in adults, who also have the most severe and prolonged symptoms. Teenagers may be incapacitated for only a few days and asymptomatic after only a few weeks.^{25,31} Equines are the only other species known to develop clinical disease (i.e., musculoskeletal symptoms) after a natural infection with Ross River virus.¹⁶

PATHOLOGY

The pathogenesis of Ross River virus disease in humans is not understood. The literature describing the pathologic process of Ross River virus

infection in mice is extensive,^{47,57,63,64,66,79,80} but almost invariably, clinical symptoms are observed only in mice infected when younger than 4 weeks of age, which have key immunologic genes silenced, or which are infected by routes that could not occur in nature and with strains of virus that have been passaged extensively in cell culture.

Synovial tissue from patients with epidemic polyarthritides may show a marked mononuclear leukocyte infiltrate with small amounts of fibrin deposition and synovial cell hyperplasia.^{46,85} No virus or viral antigen has been detected in synovial tissue from patients with epidemic polyarthritides, but a 250-nucleotide fragment of the viral genome was detected by reverse transcriptase polymerase chain reaction (RT-PCR) in synovium from 2 of 12 patients 5 weeks after the onset of symptoms.⁸⁵ Ross River virus can replicate for a similar period in human synovial cells maintained at 35°C (95°F) in vitro.⁵¹ Whether virus persists in joints as long as symptoms are present remains unclear, and ethical and technical constraints prevent this issue being explored in a systematic manner.

Fluid from affected joints consists almost entirely of mononuclear leukocytes at all stages of disease.^{20,34,36} Human synovial fibroblasts infected with Ross River virus in vitro produce elevated levels of messenger RNA (mRNA) coding for chemoattractants and other mediators, such as monocyte chemoattractant protein 1, interleukin-8 (IL-8), granulocyte-macrophage colony-stimulating factor, and tumor necrosis factor- α , but elevated levels of the proteins for which they code have not been demonstrated.⁶¹ Viral antigen can be detected (in macrophages in synovial fluid) for only 5 to 7 days after the onset of symptoms, despite the persistence of arthritis for 30 to 40 weeks.³⁷ No evidence of immune complexes or complement activation in arthritic joints has been found.

No significant levels of anti-collagen antibodies were detected in serum from epidemic polyarthritides patients.⁴⁰ The significance of elevated levels of the pattern recognition molecule long pentraxin 3 (PTX3), which has a role in all three complement pathways, in serum from epidemic polyarthritides patients remains to be elucidated.³² Neither anti-Ross River virus antibody levels nor a primary, virus-specific, cell-mediated immune response to Ross River virus infection correlated with the presence or absence of arthritis in human infections.⁶ In patients with epidemic polyarthritides, a nonspecific immunologic response (i.e., natural killer cells) correlated well with the presence or absence of arthritic symptoms.^{6,3} Functional natural killer cells have been recovered from the knee of a patient with epidemic polyarthritides,⁴⁶ and natural killer cells kill autologous synovial tissue in vitro.³

Infection of primary human osteoblasts with Ross River virus in vitro results in production of IL-6, chemokine (C-C motif) ligand 2 (CCL2), and IL-1 β and an increased ratio of receptor activator of nuclear factor- κ B (RANKL) to osteoprotegerin (OPG). Levels of RANKL proteins in synovial fluid from patients are elevated, and levels of OPG are lower than in healthy controls.¹⁸ Chen and colleagues suggested that monocytes were recruited to the site of Ross River virus infection by the chemoattractant cytokines and chemokines where they are differentiated into bone-resorbing osteoclasts.

A rash develops in approximately 30% of patients with epidemic polyarthritides.⁶⁵ The dermis underlying these lesions contains a perivascular infiltrate of CD8⁺ T cells and some monocytes and macrophages.³⁹ No immunoglobulin or complement deposition has been observed in these lesions, although Ross River virus antigen was detected in basal epidermal and eccrine duct epithelial cells.³⁹

DIAGNOSIS

The signs and symptoms of a Ross River virus infection are too non-specific to permit establishment of a diagnosis on clinical grounds alone.⁴³ Most clinical diagnoses of epidemic polyarthritides are confirmed by use of an indirect enzyme-linked immunosorbent assay (ELISA)⁷⁰ to detect Ross River virus-specific IgM antibodies in serum collected 7 to 10 days after the onset of symptoms. Various forms of this assay are available from commercial suppliers. Immunoglobulin M (IgM) can be detected for approximately 3 months after the onset of disease.¹⁰

In less than 1 of 5000 cases, anti-Ross River virus IgM antibody production may persist for years. Assays for serum anti-Ross River

virus IgA may be an alternative to IgM assays because the duration of IgA production is shorter than that for IgM.¹⁷ However, IgA assays have not been routinely adopted by diagnostic laboratories. Indirect ELISA assays that measure the avidity of anti-Ross River virus antibody can discriminate between recent and old infections with this virus.⁵²

Although virus sometimes can be isolated from seronegative, acute-phase sera,^{7,11,30,76,86} this procedure is not performed in most diagnostic laboratories. RT-PCR protocols,⁸² mostly unpublished, have been developed for the detection of Ross River virus RNA, but they are less sensitive than is virus isolation for detection of the virus and are used routinely for the diagnosis of human disease only in large, central laboratories.

Because epidemic polyarthritis is an arthritic disease, care must be taken to avoid false-positive results caused by the presence of rheumatoid factor when indirect ELISA is used to detect anti-Ross River virus IgM antibodies. Precautions include removal of IgG or rheumatoid factor before testing sera and performing tests for rheumatoid factor in parallel with ELISA.

Another source of false-positive diagnoses is the production of anti-Ross River virus IgM antibody caused by polyclonal B-cell activation after infection of a Ross River virus-immune host with Epstein-Barr virus, cytomegalovirus, *Coxiella burnetii*, or *Plasmodium* spp. Other viral infections to be considered when an Australian patient or traveler is suspected of having epidemic polyarthritis include infections with Barmah Forest, Sindbis, Kunjin, Kokobera, or rubella viruses.

TREATMENT AND PROGNOSIS

No specific antiviral therapy is available, although experimental evidence suggests that interferon- γ may ameliorate acute disease.⁸⁰ Nonsteroidal antiinflammatory medication or steroids have been used to treat patients

with severe disease or prolonged symptoms, but the therapeutic efficacy has not been evaluated in a systematic manner. A small study found that patients taking corticosteroids recovered more quickly than those using nonsteroidal antiinflammatory medication.⁶⁸ Rest while maintaining mobility and muscle tone appears to provide significant relief. Epidemic polyarthritis does not progress to chronic joint disease.

PREVENTION

A killed virus vaccine¹² was found to be safe and immunogenic in clinical trials.^{13,89} In urban areas, public health mosquito control programs reduce mosquito numbers, but prevention of mosquito exposure for those with outdoor occupations and pastimes is impossible. Personal protection (i.e., insect screening of houses, wearing of protective clothing, and application of insect repellents) is the only reliable way to avoid the risk for being infected.

175F ■ Other Alphaviral Infections

Gail J Harrison • Theodore F. Tsai

O'NYONG-NYONG

The virus name *o'nyong-nyong* is derived from the Acholi dialect of the Southern Luo language of the people of East Africa. The term means "very painful and weak," which describes the acute constitutional symptoms and polyarthritis associated with the disease of the same name.²⁰ The *o'nyong-nyong* virus (ONNV) is a mosquito-borne RNA virus of the *Togaviridae* family, genus *Alphavirus*. It is genetically and serologically related closely to chikungunya virus and is seen in Africa. Unlike most arboviruses, ONNV is transmitted by anopheline mosquitoes in an interhuman cycle analogous to that of malaria in rural Africa. Apart from the human-to-human epidemic cycle, the natural transmission cycle and involvement of other vertebrate hosts are largely unknown. There is also a suggestion that *Aedes aegypti*, a mosquito found in some parts of Europe, may be a competent vector ONNV, indicating the virus may spread outside of Africa at some point.

The virus was first isolated in June 1959 in Gulu, Uganda, when ONNV disease first came to attention in the largest arboviral epidemic ever recorded. After emerging in Uganda in 1959, the epidemic spread to South and West Africa and produced an estimated 2 million cases before the outbreak died out spontaneously 3 years later. The disease apparently had disappeared from East Africa, although the virus was isolated sporadically from mosquitoes until 1996, when the second recognized outbreak of ONNV appeared in Uganda.²⁰ It has been responsible for several outbreaks in East Africa (Kenya, Uganda, Tanzania, Malawi, and Mozambique). In October 2013, a laboratory-confirmed imported case of ONNV infection was documented in a 60-year old woman from Germany who had returned home from a vacation to Uganda, Kenya, Rwanda, and Tanzania. She developed a recurring febrile illness with malaise, arthralgias of small joints, rash, edema, lymphadenopathy, arthralgia, and nausea, and a fourfold rise in anti-ONNV immunoglobulin G (IgG) titer was documented along with ONNV-specific neutralizing antibodies.⁴¹

In 2015 through 2016, there was a minor outbreak of 51 cases of ONNV infection reported in Uganda. The ONNV is considered endemic in coastal East Africa, similar to chikungunya virus.²²

Clinically, the disease caused by ONNV is similar to chikungunya and should be considered in the differential diagnosis of acute febrile illness associated with travel to East Africa. It is also considered one of the tropical arthritogenic alphaviruses, along with chikungunya, Sindbis, Ross River, Mayaro, and Barmah Forest viruses, which have specific tropism for bones and joint tissue and can cause chronic rheumatic disease.²⁸ ONNV causes self-limited febrile illness with headache, rash, and joint pain. Lymphadenopathy is more pronounced in ONNV disease than in chikungunya and in some cases mimics the enlarged cervical lymph nodes of sleeping sickness.⁶ The joint involvement is characteristically acute polyarthritis and polyarthralgia that is symmetric and involves the small peripheral joints. It may become chronic and cause painful arthropathy.⁴⁰

The ONNV virus can be isolated from acute-phase blood samples performed in specialist public health laboratories. Detection of viral RNA by real-time reverse transcriptase polymerase chain reaction (RT-PCR) is also performed in reference public health laboratories.^{5,24} The diagnosis can be confirmed serologically by detection of ONNV-specific immunoglobulin M (IgM) and a fourfold increase in ONNV-specific IgG by immunofluorescence assay. A virus neutralization test can also be done to confirm infection. There is a serologic cross-reaction with chikungunya virus, and interpretation of serologic testing should be done in this context. Serologic cross-reactivity has led public health officials to wonder how many true ONNV infections have been misdiagnosed as chikungunya infections.

There is no specific antiviral treatment available for ONNV infection. It is a self-limited illness. The arthralgias and arthropathy may respond to analgesics and nonsteroidal antiinflammatory drugs (NSAIDs).⁴⁰ There is no vaccine for prevention of ONNV infection. Personal protective measures against malaria (e.g., bed nets, mosquito repellants, protective clothing) should be effective against acquiring ONNV infection.

IGBO-ORA FEVER

Igbo-ora virus, first detected in Igbo-Ora, a community in western Nigeria, in 1967, has been determined genetically to be a subtype of ONNV. It is transmitted by anopheline mosquitoes and (without adaptation) is nonpathogenic in suckling mice.³³ The viral transmission cycle has not been defined. Sporadic cases and small outbreaks have been reported from Igbo-Ora and Ibadan, Nigeria; the Ivory Coast; and the Central African Republic. It has been detected in humans and anopheline mosquitoes in the Central African Republic, Nigeria, and the Ivory Coast. Based on a single case description, the illness consists of fever, polyarthrititis, and pharyngitis.

BARMAH FOREST FEVER

Barmah Forest virus (BFV) is an RNA virus in the *Togaviridae* family, *Alphavirus* genus. It is named after the location in Northern Victoria, Australia, where it was first isolated in 1974. It occurs commonly in Australia, is the second most common arbovirus infection in Australia (after Ross River virus), and infects thousands annually.³⁰ BFV causes a sporadic and occasionally hyperendemic infection leading to a febrile, polyarthralgia-rash illness that is indistinguishable from Ross River fever.^{12,23,35} It was first detected in Western Australia in 1989.

The mosquito-borne viral transmission cycle of BFV shares some features with that of the Ross River virus. However, independent outbreaks have occurred in all Australian locations where both viruses are enzootic, indicating differences in their transmission cycles or human susceptibility. BFV is hosted by marsupials, especially possums, kangaroos, and wallabies. It is transmitted to humans by bites of infected mosquitoes, including *Aedes* (especially *A. vigilax*) and *Culex* (especially *C. annulirostris*). Seroprevalence for BFV usually is lower than for Ross Valley virus.

Clinically, most BFV infections are subclinical or asymptomatic. When BFV causes disease, it is similar to chikungunya and ONNV and should be considered in the differential diagnosis of acute febrile illness associated with travel to Australia. It is also considered one of the tropical polyarthritides viruses, along with ONNV, chikungunya, Sindbis, Ross River, and Mayaro viruses, which have specific tropism for bones and joint tissue and can cause chronic rheumatic disease.²⁸

BFV illness is self-limited and includes fever, malaise, rash, arthralgia, and muscle tenderness that lasts a few days to a week. The joint pain, however, may continue for 6 months in about 10% of patients infected with BFV. Anecdotal cases complicated by central nervous system signs and glomerulonephritis have been reported.^{19,35} Serologic diagnosis using detection of BFV IgG and IgM enzyme-linked immunosorbent assays (ELISAs) and microneutralization assays for acute and convalescent sera to document seroconversion is straightforward in most cases, with little cross-reaction between the viruses.⁸

There is no specific antiviral treatment available for BFV infection. It is a self-limited illness.³⁰ The arthralgias and arthropathy may respond to analgesics and NSAIDs. There is no vaccine for prevention of BFV infection. Personal protective measures against malaria (e.g., bednets, mosquito repellants, protective clothing) should be effective against acquiring BFV infection.

SINDBIS FEVER

Sindbis virus (SINV) is an enveloped RNA virus of the family *Togaviridae*, genus *Alphavirus*. The virus was named after a district in the Nile River delta north of Cairo, Egypt, where it was isolated in 1952 from *Culex* mosquitoes.⁴² It is the prototype of an antigenic complex that also includes western equine encephalitis virus and several Sindbis viral subtypes, including Ockelbo and related strains isolated from Scandinavia and the Babanki strain from West Africa.

Two SINV genotypes consisting of the South African and Scandinavian strains and the Australian and Asian strains have been defined. The close genetic relationship of the South African and Scandinavian strains indicates a recent introduction to Europe, possibly by a migrating bird.

The virus is distributed widely over four continents, although only sporadic cases have been reported from Asia and Australia. Transmission is endemic and occasionally hyperendemic in Africa and Scandinavia.¹

The virus is transmitted to birds by various species of *Culex* mosquitoes, and humans are infected when virus transmission spills out of the enzootic cycle by the intervention of bridging vectors that feed on viremic birds and later on humans.

Endemic infections occur with various intensities in areas of Africa.^{18,27} Seroprevalence rates range from a few percent to 20% in some areas. Outbreaks producing hundreds to thousands of cases have been described. Concurrent transmission with West Nile virus, transmitted in the same avian cycle, is common. In South Africa, transmission occurs during the austral summer from December to April. Infections rarely are acquired during travel.¹⁰

An endemic focus in Scandinavia (i.e., between 60 and 63 degrees latitude in Sweden) was recognized after a series of outbreaks in 1981 led to several hundred cases in Sweden, Norway, Finland, and adjacent areas of western Russia and were locally called Ockelbo fever, Pogosta disease, or Karelian fever.^{11,25,40} The seroprevalence rate is about 5% to 10%. By estimation from seroprevalence rates, 600 to 1200 clinical cases may occur annually in Sweden alone. Serosurveys indicate a wider distribution of unrecognized infection in Northern and Central Europe. Most cases occur from July to September, affecting middle-aged adults exposed to forested areas while picking berries or mushrooms or during other recreational activities. SINV outbreaks in Finland and other parts of northern Europe seem to peak at 7-year intervals and are associated with the size of grouse populations.¹⁷

Acute arthralgia and rash are the principal features of the illness.¹ They may be preceded by mild fever, headache, and myalgia, but patients can have arthralgia alone, and children can exhibit fever and nonspecific symptoms alone. The joints, especially the ankles, wrists, knees, fingers, and toes and less often the hips, shoulders, elbows, neck, and back, are involved symmetrically. The joints appear swollen, and movement is limited. The Achilles and wrist tendons can be inflamed, sometimes causing nerve entrapment and paresthesias. Some patients are confined to bed and unable to walk, but the joint pain and stiffness typically lead to a lesser degree of discomfort and compromised function.

A fine papular and sometimes pruritic rash appears on the trunk and extremities (including the palms and soles) but usually spares the face and head. After a few days, the rash develops a stained appearance and disappears. Lesions on the hands and feet may vesiculate. Joint symptoms resolve within 3 to 4 months in approximately 60% of cases; in the remainder of patients with SINV infection, symptoms may persist for 3 to 4 years.^{21,32,36,38}

A higher prevalence of HLA-DRB1*01 and autoantibodies has been reported in patients with continued joint symptoms 3 years after the initial illness in contrast to a reference population.³⁸ Muscle biopsy from a patient with prolonged weakness and in vitro experiments suggest that the virus can infect and destroy myotubes and myoblasts.³⁶ Serologic evidence of infection in patients with central nervous system signs has been reported from China.¹⁴

The illness of SINV is not differentiated easily from West Nile fever, which is transmitted under similar epidemiologic circumstances, and has been mistaken for rubella.

The laboratory diagnosis is confirmed serologically by detection of SINV-specific IgM in acute-phase serum samples. IgM is detectable for months in some patients. The virus can be isolated, although not reliably, from acute-phase capillary blood specimens and skin lesions. Viral genomic products can be detected in skin biopsy samples.¹⁶ A real-time RT-PCR assay for SINV has been used to screen for SINV in wildlife. However PCR application to the diagnosis of human SINV disease is limited because the viremia associated with SINV infection in humans is low and short lived.^{24,37}

There is no specific antiviral treatment available for SINV infection. Symptomatic treatment with NSAIDs is sufficient in most patients with a self-limited illness. Anti-tumor necrosis factor antibodies have exacerbated alphaviral infection in experimental animals and should be avoided. There is no vaccine available to prevent SINV infection. However, personal protective measures used against malaria (e.g., bed nets, mosquito repellants, protective clothing) should be effective against acquiring SINV infection. Control of water areas infected by mosquito populations should be done to reduce SINV mosquito reservoirs.¹⁷

MAYARO FEVER

Mayaro virus (MAYV) is a member of the family *Togaviridae*, genus *Alphavirus*. The virus is placed in the Semliki Forest antigenic complex; its Una subtype causes arthritis in horses.

The virus was isolated first from sporadic fever cases on Trinidad and named after the island's Mayaro district.³ It is another neglected tropical arbovirus infection that primarily affects people who live in forested areas in tropical South America, especially during the rainy season. Endemic infections with MAYV are highly prevalent in the forested areas of South and Central America, where MAYV is transmitted by *Haemagogus* spp. mosquitoes to marsupials and small mammals (e.g., monkeys), somewhat analogous to the jungle cycle of yellow fever.^{4,13,43} Seroprevalence rates increase with age to higher than 50% among native populations in some locations.

Outbreaks have occurred in Bolivia, Pará (a state in Brazil), and Surinam, principally among men occupationally exposed to forested sites, residents of adjoining villages, and travelers returning from Central America.^{9,34,39} Cases also have been reported among travelers returning to the United States, Switzerland, Netherlands, France, and Germany and should be included in the differential diagnosis of febrile illness in travelers returning from South America.³¹ Epidemic transmission was reported in the city of Manaus, Brazil, and is a risk in other *Aedes aegypti*-infested cities.²⁹ Studies from 2017 suggest MAYV infection may occur more frequently in central Brazil than previously described and may be spreading to urbanized areas, similar to the Zika virus urbanization spread in 2015.⁷

The illness associated with MAYV may be mild, with acute febrile illness and an uneventful recovery. It may also be severe and dengue-like, with fever and severe, acute polyarthritis and rash.³⁴ Joint swelling, pain, and stiffness principally involve the hands, wrists, ankles, toes, elbows, and knees. The hands may be so swollen that they cannot be closed, and joints of the lower extremities may be so painful that patients limp or are unable to walk. Milder cases can occur.

The morbilliform rash is difficult to distinguish from rubella, with individual or coalescent papular lesions occurring on the trunk and extremities and usually sparing the face. Rash occurs more often in children than in adults. Mild fever, pharyngitis, conjunctivitis, headache, retrobulbar pain, lymphadenitis, and minor mucosal and petechial bleeding occur in some patients. The constitutional symptoms resolve rapidly, but the joint symptoms may wax and wane for several weeks or months, and they may be severe and debilitating. Pneumonitis and renal dysfunction that were described in rare cases might have been caused by concurrent infections. Transient leukopenia usually develops; some patients have had mild elevations in liver enzyme activities and bilirubin concentrations. A fatal case of yellow fever was described in a patient recovering from MAYV fever.

The illness is differentiated from other tropical febrile illnesses with rash and musculoskeletal pain by the specific involvement of the joints and the sylvatic setting of exposure. Some patients have features resembling those of rubella, human herpesvirus type 6 (HHV-6), parvovirus, Epstein-Barr virus (EBV) mononucleosis, malaria, chikungunya, Zika virus, or yellow fever.

Infection with MAYV may be laboratory confirmed by isolation from acute-phase blood specimens, but laboratory confirmation by MAYV-specific IgM ELISA serology is sensitive, specific, and more practical than culture.⁷ IgG antibody may also be detected through indirect immunofluorescence assay or virus neutralization assay to document MAYV-specific seroconversion. There is no specific antiviral treatment for MAYV infection. However, thienopyridine-derivative antiviral compounds have shown promise in decreasing MAYV replication in vitro, suggesting the potential application of this class of compounds against MAYV and all alphaviruses.²

The illness is self-limited for most patients, and symptoms are treated with analgesics, antipyretics, NSAIDs, and rest. There is no vaccine to prevent MAYV infection or disease. However, personal protective measures used against malaria (e.g., bed nets, mosquito repellants, protective clothing) should be effective against acquiring MAYV infection when traveling to endemic areas.

SEMLIKI FOREST VIRUS FEVER

Semliki Forest virus (SFV) is an RNA virus in the *Togaviridae* family, *Alphavirus* genus. It was first isolated from mosquitoes in the Semliki Forest in Uganda in 1942. It causes infection and illness in humans and animals, including wild birds, rodents, domestic animals, and nonhuman primates. SFV is found in Central and West Africa, parts of Asia, and possibly in central and southern Europe, where it is transmitted principally by forest *Aedes* mosquitoes.²⁶ A rare case of inhalation transmission was reported. The virus appears to be a common cause of infection in horses and humans. The Me-Tri subtype has been implicated serologically in encephalitis cases in Vietnam; its transmission cycle has not been described.

Infection with SFV is thought to be subclinical or asymptomatic for most individuals, or it can cause a mild, self-limited flu-like illness with fever, severe and persistent headache, myalgia, and arthralgia. Fatal cases associated with meningoencephalitis have been reported.⁴⁴ It also may be severe in immunocompromised patients.²⁶ Several laboratory-acquired infections and at least one fatal case of SFV encephalitis in a laboratory worker have been reported.¹⁵

There is no known antiviral treatment for SFV infection, and no vaccine against SFV is available. However, because SFV has a broad host range and efficient viral replication, it has been developed as a vaccine vector for anticancer treatment agents and as a tool in gene therapy against glioblastoma brain tumors. Personal protective measures used against malaria and mosquito-borne arboviral infections (e.g., bed nets, mosquito repellants, protective clothing) should be effective against acquiring SFV infection when traveling to endemic areas. Laboratory workers working with SFV should take appropriate precautions to avoid skin contact or contact with aerosols from the virus.

176A ■ St. Louis Encephalitis

Kimberly C. Martin • José R. Romero

St. Louis encephalitis (SLE) virus was first identified in 1933 after an epidemic of encephalitis in St. Louis, Missouri, during August 1933.⁸⁷ Before the 1999 introduction of West Nile virus (WNV), SLE was the most important arboviral infection in the United States because of its leading role as a cause of widespread epidemics. Encephalitis is the principal clinical manifestation, although milder central nervous system (CNS) syndromes do occur, especially in children. The virus is transmitted between birds and *Culex* mosquitoes, with humans serving only as incidental, dead-end hosts.

ETIOLOGIC AGENT

The SLE virus is a member of the genus *Flavivirus* within the Flaviviridae family of viruses. SLE belongs to the Japanese encephalitis virus antigenic complex, which also includes important human pathogens such as Japanese encephalitis virus, WNV, and Murray Valley encephalitis virus.

Phylogenetic analysis of the E glycoprotein sequences from 62 strains from the United States and Central and South America identified seven genotypes corresponding to origins in the United States and South America.³⁶ A later analysis of 133 strains, including 30 novel strains from Brazil, identified an eighth genotype.⁷² Individual clades exist within each genotype.

Genotype II is more prevalent in North America, and genotypes I and III through VIII are distributed throughout the Americas.⁷² The most genetically diverse strains have only a 10.1% nucleotide divergence (i.e., 2.8% amino acid variation) in the total E gene nucleotide sequence, whereas strains within each lineage show less than a 5.5% nucleotide divergence, indicating a highly constrained viral adaptation to vector and vertebrate hosts.⁴⁹ The nucleotide diversity exhibited by SLE is substantially less than that seen for other members of the Japanese encephalitis virus antigenic complex. Strains from the three principal genotypes in the United States (I, II, and V) have different biologic characteristics. Epidemic-associated strains from the Ohio and Mississippi river basins and Florida display greater virulence in mice than do strains from the western United States associated with an endemic pattern of transmission.^{17,51} Multiple viral genotypes with distinct biologic characteristics may be transmitted in relatively delimited areas within a region as small as a county in some years and more widely in others.^{17,35}

ECOLOGY

SLE virus is transmitted in an enzootic cycle among birds and *Culex* mosquitoes in three distinct cycles associated with its four principal vector species: *Culex tarsalis* in the western and central United States, *C. pipiens* in the eastern and western United States, *C. quinquefasciatus* in the east central and Atlantic states, and *C. nigripalpus* in Florida. *C. salinarius* and *C. restuans* may have accessory roles in viral amplification and transmission (Fig. 176A.1).^{13,40,43,50,82}

In the western United States, *C. tarsalis* serves as an enzootic and epizootic vector. This species feeds chiefly on birds early in the summer and switches to mammalian hosts, including humans, in midsummer. The transmission cycles of SLE virus and WNV overlap throughout

the United States. Sparrows, finches, and other small birds and especially their nestlings are the principal amplifying hosts.⁴⁸ In the West, human infections result from encounters with the vector along natural and artificial waterways, irrigated farmland, and other breeding sites found chiefly in rural agricultural areas.

The introduction of WNV into an overlapping transmission cycle appears to have an effect of modulating SLE virus transmission because WNV-infected birds are more refractory to development of infection and viremia with SLE virus than the reverse.²⁷ In the Ohio and Mississippi valleys and on the Gulf Coast, infections are acquired in the peridomestic environment, where *C. pipiens* and *C. quinquefasciatus* are, respectively, the enzootic vectors in northern and southern states.

The mechanism by which the virus overwinters is unknown, but SLE virus has been shown to persist in overwintering *C. tarsalis* and *C. pipiens* for more than a month.³ Vertical or transovarial transmission has been detected under laboratory conditions in *Culex* species.^{3,30,46}

The intermittent occurrence of urban SLE outbreaks has been associated with climatic factors, such as a severe winter freeze in the 1 to 2 years before an outbreak or an antecedent mild winter, wet spring, and dry, hot summer.^{21,50} Snowpack and the resultant availability of irrigation water and an area supportive of mosquito breeding appear to be highly predictive of viral transmission in southern California.⁸⁰ In a model of global warming, SLE transmission is predicted to move to northern latitudes and, in existing endemic areas, to become seasonal in the spring and fall.⁶⁶ Periods of drought followed by a briefer wet interval have been associated with viral transmission in Florida.^{20,76}

EPIDEMIOLOGY

The epidemiologic patterns of SLE virus transmission reflect human interactions with reservoirs of the virus and its principal mosquito vectors.^{39,41,50,82} In western states (Figs. 176A.2 and 176A.3), perennial transmission of SLE virus leads to an endemic pattern of transmission, but epidemics are limited by a high level of immunity in the population.^{68,81} Infections occur chiefly in rural areas in association with the habitat of the vector. SLE outbreaks typically have taken place in rural agricultural areas and their small towns.³⁸ Studies in Texas indicated that an overlap of urban and rural cycles contributed to an urban outbreak in Dallas after introduction of the virus to the urban *C. quinquefasciatus* cycle from rural *C. tarsalis*.^{33,39,40}

Epidemics frequently have occurred in urban locations or their peripheries. In 1975, a nationwide epidemic led to outbreaks in Houston, Chicago, Memphis, and Detroit and to smaller outbreaks in rural towns throughout the South and Midwest, resulting in more than 2000 cases (Fig. 176A.4). Outbreaks in large urban centers usually have been associated with attack rates of fewer than 40 cases per 100,000 residents and often have clustered in low socioeconomic status areas.^{19,33,50,53,62,84,82,90} The US SLE outbreak in 2015 occurred concurrently with WNV in the Phoenix, Arizona, area and resulted in 19 cases.^{11,14,23}

In modern urban outbreaks, homelessness and infection with human immunodeficiency virus (HIV) have been the principal risk factors for acquiring SLE.^{59,86} However, in the 1933 St. Louis outbreak, attack rates

Keywords

Murray Valley encephalitis virus
arbovirus
mosquito transmission
Australia

were highest in wealthy areas where open sewers, streams, ponds, and weeds were prevalent. In other outbreaks, lush vegetation around houses, which provides shelter for *C. nigripalpus*, and closed sewer systems clogged with grass clippings were factors associated with high attack rates in upper socioeconomic areas.^{20,49}

In outbreaks of disease from *C. pipiens* and *C. quinquefasciatus*, epidemic attack rates are 1.2 to 3 times higher among females than males, possibly reflecting increased exposure of females to these peridomestic vectors.^{45,50,83} In western *C. tarsalis*-borne outbreaks, attack

rates are usually higher among males.^{38,68} A similar observation has been made in Florida, where SLE attack rates are highest among working-age men.^{22,49,57} *C. nigripalpus* and *C. tarsalis* are most active in the twilight hours, and outdoor activity during these periods is associated with a greater risk of exposure.

Most cases (>80%) occur during the months of July through September.⁶⁷ However, in Florida, epidemics have continued through mid-December.^{49,75} In the 1975 nationwide epidemic, outbreaks appeared first in the southeastern states in June, followed by an appearance in northern foci later in the summer and fall.⁵⁰

From 2004 to 2013, 92 cases of SLE were reported to the Centers for Disease Control and Prevention (CDC). This included 25 cases of nonneuroinvasive and 67 cases of neuroinvasive disease, with an average of 7 neuroinvasive cases reported annually. Six states accounted for almost 80% of neuroinvasive cases during this period (in decreasing number): Arkansas, Texas, Louisiana, Mississippi, Arizona, and Michigan.¹² Within states reporting infections, cases were geographically restricted (see Fig. 176A.3).¹² Outbreaks occurring in 2014 and 2015 resulted in 10 and 19 cases, respectively.^{11,14} In the latter, 17 were neuroinvasive. SLE has reemerged in areas where it had been absent for decades. In 2010, the District of Columbia reported two cases of nonneuroinvasive SLE. They were the first case reports from this jurisdiction since 1975.¹⁰

Although a case of neuroinvasive SLE in an infant as young as 19 days has been reported, the most important risk factor for acquiring neuroinvasive disease is advanced age.^{41,50,89} Age-specific attack rates are lowest for children and rise steadily throughout adulthood, with attack rates 5 to 40 times higher in people older than 60 years than in those younger than 10 years of age. During outbreaks, infections occur uniformly in all age groups, with as many as 300 asymptomatic infections for each clinically apparent case. The higher clinical attack rates among the elderly are a function of susceptibility, not exposure.^{41,50} The clinical expression of illness is more severe and the case-fatality rate is also highest among the elderly. The biologic basis for this age-related risk probably reflects aging of the immune system and comorbidities compromising cerebrovascular integrity.⁹

In the West, where SLE infections are endemic, an increasing level of immunity associated with length of residence leads to an adult population with lower susceptibility (i.e., 11% in the most recent serosurvey).⁶⁸ Consequently, cases often are seen in children and young adults. In a Florida outbreak, immunity to other flaviviruses (mainly from previous dengue infection) was shown to protect against the acquisition of SLE.⁶

FIGURE 176A.1 Transmission cycles of St. Louis encephalitis virus in North America. *Culex* mosquito vectors cover different geographic areas: *C. tarsalis* in the West, *C. pipiens* and *C. quinquefasciatus* in the Ohio and Mississippi River Valleys, and *C. nigripalpus* in Florida. Epidemics occur when intense viral transmission in the enzootic cycle spills over and results in human infections. The viral overwintering mechanism, possibly in mosquitoes or persistently infected vertebrates, has not been proved (dashed lines).

FIGURE 176A.3 Reported cases of St. Louis encephalitis virus neuroinvasive disease by state from 2004–13. Cases were reported by county of residence. Neuroinvasive disease includes encephalitis, meningoencephalitis, or meningitis. (From Centers for Disease Control and Prevention. St. Louis encephalitis virus neuroinvasive disease average annual incidence by county, 2004–2013. https://www.cdc.gov/sle/pdf/sle_county_map-04-13.pdf.)

FIGURE 176A.4 Reported St. Louis encephalitis cases by year in the United States, 1964–2010. A nationwide epidemic in 1975 produced more than 2000 cases.

Cases of SLE have been reported in the Caribbean and South and Central America (i.e., Jamaica, Suriname, French Guiana, Argentina, Brazil, and Peru).^{1,22,28,78} Increasing seroprevalence rates observed with increasing age indicates a higher frequency of endemic infection than is clinically apparent.^{1,79} SLE is an emerging cause of arboviral disease in South America and has been responsible for sporadic cases and several outbreaks.^{22,54,78} In 2005, the largest outbreak reported occurred in Cordoba, Argentina, resulting in 47 laboratory-confirmed or probable cases; 11 of the infections occurred in children. Nine adults died in this outbreak.⁷⁹ A smaller outbreak in Buenos Aires, Argentina, in 2010

resulted in 13 confirmed cases.⁷⁴ These sporadic SLE outbreaks principally have resulted in mild febrile illnesses that have been clinically confused with dengue. SLE and dengue coinfection has been demonstrated in Brazil.³²

CLINICAL MANIFESTATIONS

Clinical manifestations range from a mild influenza-like illness to fatal encephalitis.^{7,64,71,90} A case definition that stratifies cases into clinical syndromes of encephalitis, aseptic meningitis, and febrile headache⁷

BOX 176A.1 Definitions of Clinical Syndromes Caused by St. Louis Encephalitis

Encephalitis^{a,b}

Acute febrile illness (oral temperature $\geq 37.8^{\circ}\text{C}$ ($\geq 100^{\circ}\text{F}$))

One or more signs in either of the following categories:

Altered level of consciousness (i.e., confusion, disorientation, delirium, lethargy, stupor, or coma)

Objective signs of neurologic dysfunction (i.e., seizure, cranial nerve palsy, dysarthria, rigidity, paresis, paralysis, abnormal reflexes, or tremor)

Aseptic meningitis^a

Acute febrile illness

Signs of meningeal irritation (i.e., stiff neck with or without Kernig or Brudzinski sign)

No objective signs of neurologic dysfunction

Febrile headache^a

Acute febrile illness

Headache (may have other systemic symptoms such as nausea or vomiting)

No signs of meningeal irritation or neurologic dysfunction

^aCerebrospinal fluid pleocytosis is seen in patients with encephalitis and aseptic meningitis; it also may be found in patients with the syndrome of febrile headache.

^bIncluding meningoencephalitis and encephalomyelitis.

Modified from Brinker KR, Monath TP. The acute disease. In: Monath TP, ed. *St. Louis encephalitis*. Washington, DC: American Public Health Association; 1980:503–34.

FIGURE 176A.5 Distribution of St. Louis encephalitis cases by clinical syndrome and age. Although mortality rates and disease severity increase with age, most pediatric cases are clinical encephalitis. (Data from Zweighaft RM, Rasmussen C, Brolnitsky O, et al. *St. Louis encephalitis: the Chicago experience*. *Am J Trop Med Hyg*. 1979;28:114–8.)

(Box 176A.1) has proved useful in surveillance (Fig. 176A.5). Although children as a group exhibit milder symptoms, encephalitis develops in more than one half of confirmed and presumptive pediatric cases, and 95% have objective clinical signs of CNS infection.^{4,5,79,90}

SLE cannot be easily differentiated from other viral CNS infections on the basis of clinical features. Photophobia, headache, fever, nausea, vomiting, malaise, and neck stiffness are typical early symptoms. In approximately one half of reported cases, an abrupt onset of weakness, incoordination, disturbed sensorium, or other neurologic signs may

occur, but equally often, patients have nonspecific symptoms with subtle changes in coordination or mentation during a prodromal phase lasting several days to more than a week. Seizures have been reported in a third of adult cases.⁸⁶

In addition to fever of abrupt onset and signs of meningeal irritation, patients almost uniformly exhibit alterations in state of consciousness such as restlessness, confusion, lethargy, delirium, or coma. Neurologic examination usually reveals general weakness, hyperreflexia, and tremulousness, but focal deficits are unusual findings. Cranial nerve palsies, especially those involving nerves VII, IX, and X, occur in 10% to 25% of cases.⁷ Clinical signs of increased intracranial pressure have been reported in a few patients.

Unusual localizing neurologic signs have been described in patients with involvement of the midbrain, thalamus, or brain stem. In a 4-year-old girl, paralysis of upward gaze was associated with a brain stem infection.³⁵ A 14-year-old boy with acquired parkinsonism attributed to SLE infection has been reported.⁶³ Ataxia has been observed in a fourth of the cases involving children, and several cases of opsoclonus have been reported for young adults.^{25,26,86} In a series of 26 children with SLE, seizures were observed in eight patients, six of whom had focal seizures; however, enteroviruses were isolated concurrently from the stool in five of the eight patients.^{4,61} It is not known whether they had enteroviral CNS infection. A confirmed case of SLE causing a seizure has been reported in a neonate.⁸⁹ In most cases, the fever abates 4 to 7 days after onset, and clinical improvement is evident early in the second week of illness. Polyradiculopathy and transverse myelitis have been reported.^{5,73}

The peripheral leukocyte count is elevated modestly, with a shift to the left for most patients. Cerebrospinal fluid (CSF) usually contains fewer than 100 leukocytes/mm³, but may, in some cases, contain fewer than 10 cells/mm³. Occasionally no cells are discovered in the CSF. An increasing ratio of mononuclear to polymorphonuclear cells is observed on successive examinations. The CSF protein level rarely exceeds 200 mg/dL, and hypoglycorrhachia is unusual.⁷

In one series, elevated serum aldolase levels suggested a myopathic process, and muscle biopsy and electromyography disclosed lower motor neuron dysfunction, possibly from spinal root involvement. Moderate transaminase elevations have been reported in 19% to 48% of adult patients. Decreased serum osmolality attributed to inappropriate secretion of antidiuretic hormone was observed in one fourth to one third of cases in two series.^{7,8}

Urinary incontinence, frequency, or retention and pyuria or proteinuria have been reported for adult patients, and viral antigen was detected on cells in the urinary sediment by immunofluorescence in one report.⁴² Lower motor neuron lesions might have been the mechanism for bladder symptoms in some patients.

Electroencephalographic abnormalities have included focal discharges, including periodic lateralized epileptiform discharges, but they more consistently show diffuse generalized slowing.^{4,8,86} Computed tomography scans may be normal, but magnetic resonance images have disclosed T2-weighted hyperintense abnormalities in the substantia nigra, consistent with edema.¹⁶

PATHOLOGY

Pathologic changes are found predominantly in the midbrain, thalamus, and brain stem but are also seen in the cerebral cortex and cerebellum. Lesions are observed in the spinal cord in some cases.^{70,77,80} The leptomeninges are affected to some degree by edema, small hemorrhages, and round cell infiltration.

Perivascular and parenchymal inflammation is prevalent in the brain nuclei and scattered in the white matter of the brain stem and spinal cord and in subcortical and deep cerebral areas. Nodular collections of inflammatory cells composed of lymphocytes, microglial cells, and monocytes are found near to or surrounding degenerating neurons characterized by eccentric nuclear displacement, nuclear pyknosis, and cellular contraction. Vascular infiltrations and thrombosis have not been described as they have in cases of western equine encephalitis (WEE) and eastern equine encephalomyelitis (EEE). Focal demyelination, which is observed in WEE, has not been characteristic of SLE. Transmission

electron microscopy may provide a pathologic diagnosis using tiny tissue fragments.¹⁸

PATHOGENESIS

After infection, viral replication occurs locally and in regional lymph nodes. After this eclipse phase, blood-borne (viremic) dissemination ensues, with secondary sites of replication occurring in muscle, endocrine, lymphoreticular, and other tissues, and in less than 1% of infections, replication occurs in the CNS. Vascular endothelial cells may have a role in actively transporting virus from the capillary lumen to the brain and in supporting secondary viral replication.²⁴ Conditions that compromise cerebrovascular integrity and disrupt the blood-brain barrier may predispose to neuroinvasion. For example, concurrent CNS cysticercosis can be a risk factor for acquiring Japanese encephalitis, a related flaviviral infection. Although some experimental studies suggest that CNS invasion occurs through the olfactory epithelium, pathologic studies of Japanese encephalitis cases indicate widespread involvement of the brain stem, deep nuclei, and cortex, which is most consistent with hematogenous infection.

Recovery from flaviviral encephalitis depends on early intrathecal synthesis of antibodies and viral clearance by macrophages. The inflammatory response in related CNS infections consists of helper-inducer T cells and, to a lesser degree, B lymphocytes infiltrating the perivascular space and parenchyma from the blood. Macrophages and activated microglial cells in the perivascular space and parenchyma, respectively, are responsible for viral clearance.

Outcome is determined by the comparative rates of viral spread and neuronal infection, the migration of inflammatory cells into the CNS, and the rapidity of the antibody response. Production of interferon is elicited in the brain of human SLE patients, but its role in limiting the spread of virus in the CNS is unclear.⁴³ The clinical course of SLE in HIV-infected persons has not been significantly different from that of other cases; however, few patients have been studied.⁸⁵

Resistance and susceptibility to some flaviviral infections in mice have been linked to genes associated with permissiveness to infection and the immune response. Environmental factors that influence susceptibility to flaviviral infection in experimental models include stress from cold or isolation, reticuloendothelial cell blockade, and heavy metal intoxication.

DIAGNOSIS

A laboratory diagnosis of SLE usually is made serologically, although virus rarely has been recovered from blood in the acute phase of illness.³⁹ Virus can be sought from brain and other organs obtained by biopsy or at autopsy by inoculation of Vero cell cultures and suckling mice intracerebrally.³⁷ Viral antigen has been demonstrated in brain sections and in urinary cell sediment.^{37,69} The clinical sensitivity of nucleic acid amplification tests (NAATs) is greater than that of antigen detection and viral culture using cell culture or suckling mouse inoculation,³⁷ although the ultimate sensitivity of NAATs depends on the dynamics of viral replication and host tropism.

Serologic studies comparing antibody titers in paired specimens collected during the first week of illness and 2 to 3 weeks later are considered the most appropriate for establishing the diagnosis.³⁷ Hemagglutination inhibition, complement fixation, and neutralizing antibody assays are used primarily in reference laboratories. A single immunoglobulin M (IgM) assay may be sufficient to establish the diagnosis in many cases. SLE-specific IgM capture enzyme-linked immunosorbent assay (ELISA) is the preferred serologic screening procedure.^{37,52} Serum and CSF samples should be tested.

Intrathecal production of virus-specific IgM reflects recent infection because virus-specific IgM can be detected in serum or CSF in 75% or more of specimens obtained within 4 days of onset. In most patients, IgM levels decline in the convalescent sample and disappear approximately 4 months after onset, although IgM persisted at high titer in a few patients for 6 months.⁸⁴ In areas where SLE is endemic, virus-specific IgM carried over from the previous transmission season can lead to an erroneous diagnosis. The indirect immunofluorescent antibody procedure

offers a similar capacity for rapid diagnosis, but it is less sensitive than ELISA, and IgM rheumatoid factor can lead to a false-positive result. Differentiation of antibody responses to WNV, particularly during simultaneous outbreaks of the infections, has been aided by development of a duplex immunoassay.^{34,45}

The serologic response in a primary flavivirus infection is usually type specific, but repeated infections lead to broad heterologous responses that are often difficult to interpret. Human infections with indigenous flaviviruses (e.g., Rio Bravo, Powassan) other than SLE are rare occurrences. However, in patients with antecedent yellow fever immunization or infection with dengue virus acquired in areas of the United States where dengue was previously endemic and recently reemergent (e.g., Texas, Florida) or acquired during travel or residence abroad, a broadly reactive flavivirus antibody response may obfuscate the diagnosis. Recent immigrants with preexisting dengue antibodies are the most common source of flaviviral antibodies in most areas of the United States.

DIFFERENTIAL DIAGNOSIS

In an endemic setting, clinicians should consider SLE principally in the differential diagnosis of patients with aseptic meningitis or acute encephalitis. However, in the context of an outbreak, the diagnostic threshold should be lowered to include patients with less specific findings, especially acute febrile illnesses with headache and patients who exhibit confusion or are encephalopathic without fever. Increased suspicion of SLE in mildly ill patients should be directed particularly at children and young adults, in whom the infection often manifests without meningoencephalitis. In South America, SLE is a sporadic cause of acute febrile illness that as a syndrome has many non-vector-borne and vector-borne causes, including dengue.^{44,81}

The clinical findings of SLE cannot be easily distinguished from those of other CNS infections, but focal neurologic deficits are less characteristic of SLE and suggest other diagnoses.⁵⁵ The combination of global confusion and tremulousness in SLE can suggest a metabolic encephalopathy, and in elderly patients, the initial manifestations of SLE can overlap with the signs and symptoms of a cerebrovascular accident.

WNV encephalitis and SLE have virtually identical clinical findings, predilection for the elderly, and other epidemiologic features, including late summer seasonality, an urban locus of epidemic transmission, and similar *Culex*-bird transmission cycles, and individual cases cannot be differentiated except by specific laboratory testing.^{34,45,47}

The progression of symptoms and localizing signs associated with herpes simplex viral encephalitis contrasts sharply with the clinical findings in SLE, in which localizing signs are less often demonstrated. Enteroviral infections have overlapping summer seasonality but often are associated with clustering of illnesses in families and other epidemiologic clues of person-to-person spread. Skin eruptions, respiratory symptoms, pericarditis, myocarditis, and conjunctivitis are helpful distinguishing characteristics. Concurrent enterovirus infection and SLE can be associated with an increased risk of seizures during the acute phase of illness.^{4,61} Enteroviral infections can be confirmed by detecting viral genomic sequences in CSF or blood by polymerase chain reaction or by recovery of virus from CSF or blood. Primary HIV, human herpesvirus 6, and mumps virus infections are other common infections that should be entertained in the differential diagnosis. One third of patients with mumps encephalitis do not have associated parotid gland swelling.

Adenoviral encephalitis is a rare infection in children, more severe than SLE, and sometimes associated with hepatic and other extraneural sites of infection. Lymphoreticular involvement and typical hematologic features suggest the clinical diagnosis of Epstein-Barr virus infection. Rabies virus encephalitis should be considered if the clinical picture is one of a progressive encephalitis.

Partially treated bacterial meningitis and parameningeal pyogenic infections are the principal bacterial causes to exclude. Cat-scratch disease can manifest as fever and encephalopathy mimicking arboviral encephalitis.⁵⁸ Seizures associated with *Shigella* enteritis and ataxia associated with typhoid fever can be interpreted as a primary CNS infection. Tuberculous meningitis is typically a subacute illness; evidence

of active extraneural sites of infection should be sought. A low CSF glucose level is a clue to the diagnosis.

In urban areas or where parental occupational exposure may occur, lead intoxication remains an important potential cause of encephalopathy. Hyperthermia associated with sustained exposure to elevated environmental temperature likewise may lead to encephalopathy with seizures, signs of raised intracranial pressure, and evidence of hepatic dysfunction. This constellation of symptoms also can suggest Reye syndrome, although this disease typically occurs in the winter and spring after a respiratory viral infection, particularly influenza virus, and is characterized by hypoglycemia and an elevated blood ammonia level. Patients with salicylism exhibit similar clinical findings, but a history of salicylate ingestion, an elevated anion gap early in the course of illness, and an elevated blood salicylate level should suggest that diagnosis.

TREATMENT

Supportive therapy is aimed at maintaining cardiorespiratory function, ensuring fluid and electrolyte balance, controlling seizures, and monitoring and maintaining normal intracranial pressure.⁴⁷ No specific antiviral therapy is available.

PROGNOSIS

The principal risk factor for a fatal outcome is advanced age (see Fig. 176A.5).^{19,33,50,53,62,84,82,90} Among all cases reported to the CDC from 1955 to 1971, 8% of the patients died, but the age-specific mortality rate for people 60 years of age or older was 19.5%. In the decade from 2004 to 2013, the mortality rate was only 2.2% for SLE-infected subjects.¹⁵ Fatality rates as high as 38% to 80% were recorded in the 1933 St. Louis outbreak for patients who were 60 to 89 years of age. Mortality rates for children have ranged from 2% to 5%, with the highest risk for children younger than 5 years of age. The overall case-fatality rate in an outbreak in Hermosillo, Mexico, that involved principally children was 20%.¹⁹ The high fatality rate in this instance is anomalous because fatality rates are usually lower in *C. tarsalis*-borne SLE outbreaks in the West.

Coma, a low CSF leukocyte count (<100 cells/mm³), and underlying hypertensive vascular disease have been factors associated with fatal outcomes for adults.⁶ For children, the risk factors for death have not been described.

Recovery from SLE usually is complete or associated with sequelae such as emotional disturbances, dizziness, headache, memory impairment, and tremor.^{2,29,31,56} In one study of 193 cases, 25% of children who were 1 to 4 years of age at the time of infection had serious neurologic sequelae, which was the highest rate for any age group.⁶⁰ The incidence of sequelae was 10% for children 5 to 9 years of age. Children who were younger than 1 year at the time of infection appeared to be spared serious sequelae.

Deficits in motor and intellectual function were reported in some cases. Seizures were not a significant residual abnormality. The same cohort monitored at intervals of 6 months to 14 years had no perceptible residual differences in intelligence quotient in contrast to the normal

population. In a case report, persistent ataxia of the extremities and trunk and dysarthria were reported as residual findings for a 54-year-old patient due to postinfectious encephalomyelitis temporally associated with SLE.^{34,75}

No deleterious effects of SLE on the outcome of pregnancy have been reported. However, infection with Japanese encephalitis virus in the second trimester resulted in transplacental viral transmission and abortion, whereas infection in the third trimester was not associated with fetal damage. Prenatal Zika virus infection, another member of the family Flaviviridae, has been casually linked to microcephaly and other severe brain anomalies.⁶⁵

PREVENTION

Preventive public health efforts have focused on surveillance of viral activity in the enzootic cycle to predict epidemic activity. In many east-central states, weekly serologic surveys of captured wild birds and sentinel chickens are conducted to detect rising seroprevalence rates that reflect viral amplification³³ and an increased risk for human infection. The abundance of female vector mosquitoes and increased viral infection rates in vectors have been correlated with the risk of epidemic transmission.⁸⁸

When viral activity is elevated, ground and aerial application of insecticides is aimed at reducing the infected adult vector population. If insecticides are applied early enough, viral amplification can be potentially attenuated and epidemic transmission aborted.

Avoidance of outdoor activity during the twilight and evening hours, use of repellents appropriately, and repair of screens or installation of air conditioners in residences are simple but effective measures that reduce exposure to adult mosquitoes. Improvement of drainage and removal of containers that can serve as mosquito breeding sites are important steps in preventing the disease.

A vaccine is not available. Vaccination of the general public is not a realistic preventive measure because of low attack rates and the intermittent and focal nature of outbreaks.

176B ■ West Nile Virus

José R. Romero

HISTORY

West Nile virus (WNV) was isolated first from the blood of a 37-year-old African woman in December 1937 in Omongo, West Nile district, in the Northern Province of Uganda while researchers were attempting to isolate yellow fever virus.²⁰⁰ In the same report, these investigators demonstrated that sera from patients recovering from Japanese encephalitis virus could neutralize WNV. Shortly thereafter, this finding was confirmed and expanded to document that WNV was antigenically related not only to Japanese encephalitis virus but also to St. Louis encephalitis virus.¹⁹⁹

In 1950, Melnick and coworkers¹⁴¹ isolated WNV from the blood of three healthy children in Egypt, thereby demonstrating that WNV was not confined to a single geographic location. Before 1999, WNV was known to be endemic to Africa, the Middle East, Europe, west and central Asia, and Oceania. With its incursion into the United States in 1999^{9,156} and subsequent spread throughout North America, Central America, and the Caribbean,^{114,174} WNV has established a worldwide distribution.

The first reports of WNV as a cause of outbreaks of febrile illness came from Israel in the early 1950s and ultimately led to its being

associated with a clinical entity coined West Nile fever.^{19,77} Studies performed by Taylor and colleagues²⁰⁶ at the US Naval Medical Research Unit in Egypt in the early 1950s provided information about the epidemiology of WNV infection and clinical picture of West Nile fever in children. This information was augmented by the seminal report by Marberg and colleagues¹³⁶ describing the clinical characteristics of serologically and virologically confirmed cases of West Nile fever among adolescent and young adult military personnel during a 1953 epidemic in Israel. Sporadic reports of central nervous system (CNS) complications associated with WNV infection followed closely after the early clinical descriptions of West Nile fever and pointed to the neuropathogenic potential of WNV.^{18,87,202-204} Further characterization of West Nile neuroinvasive disease (encephalitis, meningitis, acute flaccid paralysis) followed as additional outbreaks of WNV were reported.

Outbreaks of WNV have occurred worldwide. Notable human outbreaks include Israel, 1951 to 1954, 1957, and 2000; France, 1962; South Africa, 1974; Algeria, 1994; Tunisia, 1997; Romania, 1996; and Russia, 1999.^{19,49,60,65,87,168,209} Two of the largest epidemics recorded occurred in South Africa in 1974 and the United States in 2003. During the former, an estimated 18,000 cases of West Nile fever occurred.⁸⁷

After the introduction of WNV into the North American continent in 1999, cases of West Nile fever and neuroinvasive disease remained at relatively low levels through 2001 and exploded in 2002 and 2003 when 4156 and 9862 cases, respectively, of WNV infection were reported to the Centers for Disease Control and Prevention (CDC) (Table 176B.1).⁴⁶ The 2002 epidemic of WNV in the United States resulted in the largest epidemic of neuroinvasive West Nile disease ever recorded, with nearly 3000 cases reported.⁴⁶ Currently, WNV has superseded all autochthonous North American arboviruses as the single most important cause of arboviral disease in the United States.¹³⁰ The

magnitude of the cumulative number of WNV infections that occurred in the United States from 1999 to 2014 can be estimated from the studies suggesting that there are 30 to 70 nonneuroinvasive WNV disease cases for every case of neuroinvasive disease. Extrapolating from a total of 18,810 neuroinvasive disease cases reported to the CDC during the 16-year period,⁴⁶ an estimated 564,300 to 1,316,700 cases of nonneuroinvasive disease might have occurred.

VIROLOGY

WNV is a member of the Flaviviridae family of RNA viruses.¹²⁷ The viral family is composed of three genera: *Flavivirus*, *Pestivirus*, and *Hepacivirus*. WNV is a member of the *Flavivirus* genus and falls within the Japanese encephalitis virus serocomplex, along with Cacipacore, Japanese encephalitis, Kunjin, Murray Valley encephalitis, St. Louis encephalitis, Usutu, and Yaoundé viruses. Kunjin virus, which is endemic to Australia and Asia, is a subtype of WNV. Members within the Japanese encephalitis virus serogroup are antigenically related to each other.

WNV is a spherical, enveloped virus measuring approximately 50 nm in diameter. The viral envelope is derived from the lipid bilayer of the host cell and surrounds the approximately 25-nm nucleocapsid core of the virion. The host cell–derived envelope is modified by the insertion of two viral proteins: E (envelope protein) and M (membrane protein).

The genome of WNV is a single-stranded, positive-sense (messenger sense) RNA molecule measuring 11,029 nucleotides in length (Fig. 176B.1).^{120,127,132} Two noncoding regions (5' NCR and 3' NCR) flank the 10,302-nucleotide viral single open reading frame and measure 96 and 631 nucleotides, respectively. The 5' and 3' NCRs contain conserved RNA secondary structures that play important roles in

TABLE 176B.1 West Nile Virus Infections in the United States, 1999–2014				
Year	Total Cases	Total Deaths	Neuroinvasive Disease	Nonneuroinvasive Disease

FIGURE 176B.1 Organization and protein products of the West Nile genome.

translation and replication. The open reading frame is organized as 5'-C-prM-E-NS1-NS2A-NS3-NS4A-NS4B-NS5-3' and is transcribed into a single polyprotein of 3434 amino acids encoding three structural and seven nonstructural proteins.^{120,127} The N-terminal portion of the polyprotein consists of viral structural proteins, whereas the remainder of the protein contains the nonstructural (NS) proteins. The viral polyprotein is cotranslationally and posttranslationally processed by host proteases and the viral protease NS2B-NS3 to yield three structural (i.e., E, premembrane [prM], and C) and seven NS (i.e., 1, 2A, 2B, 3, 4A, 4B, and 5) proteins.

Viral attachment, endocytosis, membrane fusion, and viral assembly are mediated by the E protein. The search for the cellular receptors of WNV has identified the integrin $\alpha_5\beta_3$ (vitronectin receptor) as the primary cellular receptor for lineage 2 WNVs.⁵⁰ The lectins DC-SIGNR and DC-SIGN are capable of binding WNV and promoting infection in vitro.⁵⁷ In addition, WNV has been shown to interact with several other cell surface proteins, but the whether they are physiologically relevant in vivo remains to be determined.¹⁶⁶ When bound to its receptor, WNV gains entry into the cell through endocytosis; after a pH-dependent change occurs in the conformation of the E protein, the viral and host endosomal membranes fuse. The viral nucleocapsid is then released into the cytoplasm of the cell. Viral replication is thought to occur on the membrane of the rough endoplasmic reticulum. The C or capsid protein binds to the viral RNA genome and forms a ribonucleoprotein complex required for packaging of the genome.¹⁵⁰ The immature virions are assembled, accumulate in vesicles, and bud into the endoplasmic reticulum. The immature virions are processed as they traverse the secretory pathway. Immature viral particles contain a prM protein that blocks premature viral fusion by the E protein. The prM protein is cleaved to the M protein by the trans-Golgi protein furin during the egress of the mature virion from the secretory pathway. Virions are transported to the cell membrane in vesicles and ultimately released through exocytosis or budding.

The NS proteins regulate viral transcription and translation, as well as attenuate host immune responses to WNV.^{127,185} The NS1 protein serves as a cofactor for the viral replicase and modulates the host innate immune response by inhibition of TLR3 signal transduction.²²² NS1 can also bind complement factor H, thereby disrupting alternate complement pathway.¹³² Host interferon (IFN) responses are inhibited by NS2A through inhibition of IFN- β promoter activity. This protein also may play a role in viral assembly. The NS3 protein is a serine protease and requires NS2B as a cofactor for activity. It also possesses NTPase and helicase activities. NS proteins 4A and 4B modulate IFN signaling. The NS5 functions as the RNA-dependent RNA polymerase and a methyltransferase. The NS5 protein from the virulent WNV strain NY99 is an antagonist of type 1 IFN-mediated JAK-STAT signal transduction.¹²¹

Phylogenetic analysis of WNV isolates from around the world has demonstrated the existence of up to six lineages.^{120,135,167} Lineages 1 and 2 constitute the major lineages. Strains that make up lineage 2 were originally thought to be found exclusively in sub-Saharan Africa and Madagascar. However, isolates from this lineage have been found in recent outbreaks of human disease in Russia, Greece, Italy, Romania, and South Africa. Lineage 1 strains are found in geographically dispersed regions around the world and can be subdivided into two clades.¹²⁰ The clade can be further subdivided into six clusters (1–6). WNV strains from Africa, Europe, the United States, the Middle East, and Russia cluster within clade 1a. Kunjin virus and India WNV strains form clades 1b and 1c, respectively. WNV strains isolated from birds and a human during the 1999 outbreak in the United States and a WNV strain isolated in 1998 from a dead goose in Israel have been shown to be closely related.¹¹⁹ Phylogenetic analysis of the prM protein and E glycoprotein demonstrated that they share more than 99.8% nucleotide homology, indicating that the North American strain of WNV almost certainly originated in the Middle East. Analysis of US WNV isolates has demonstrated a slowly evolving nucleotide divergence. The initial WNV strain in the United States, NY99, was displaced in less than 4 years by the current dominant genotype WN02.

Genetic correlations appear to exist between genotype/lineage and virulence/fitness phenotype.^{95,120,135,167} Neurovirulence data by use of a murine model indicates that lineage 1 strains of WNV are more

neuroinvasive than are those of lineage 2.¹⁵ Nucleotide changes in the 3' noncoding region and amino acid substitutions in the nonstructural and envelope proteins have been associated with increased morbidity and viral load in American crows, decreased incubation time for infection until transmission of WNV by *Culex pipiens* mosquitoes, and modification of the host IFN signaling cascade. These changes have given rise to attenuated genotypes of WNV as it has spread across the United States.

EPIDEMIOLOGY

In temperate climates, WNV infections occur seasonally during the summer months, coinciding with periods of increased activity of its mosquito vectors. The peak period of activity for transmission of WNV to humans in the United States generally is from July through September.^{130,45} As WNV has spread southward in the United States, the period of reported transmissions has increased, with human cases being reported as early as April and as late as December.⁸⁹ Year-round transmission may be possible in tropical climates.

Infections of humans (i.e., epizootic infection) by WNV are incidental to its enzootic life cycle and, with rare exception, result in a "dead-end" infection without subsequent human-to-human transmission. Epizootic transmission of WNV occurs when sufficient numbers of mosquitoes that bite both birds and humans become infected to allow transmission to humans. Important risk factors for the acquisition of human WNV infection are the amount of time spent outdoors when mosquitoes are biting; the presence of dead birds in the neighborhood; the exposure to mosquitoes; and the land cover, water, and soil suitable for harboring potentially infected mosquitoes.^{26,51,84,149}

Climate and rainfall can influence the distribution and timing of WNV outbreaks. The competence of *Culex* mosquitoes as vectors increases at higher temperatures. Drought brings mosquito vectors and their hosts in closer contact.²¹ Elevated environmental temperature accelerates viral replication within mosquito vectors and decreases the time span of the reproductive feeding cycle of *Culex* mosquitoes.^{62,85,109,177} Increases in WNV infections have been associated with economic factors, such as the downturn in the housing market and delinquent mortgages, which has led to large numbers of neglected residential swimming pools in some areas.¹⁷⁸

The enzootic cycle of WNV requires replicative phases in its mosquito vectors and avian (or other) hosts. After WNV-infected blood meal has been ingested, the virus penetrates the mosquito's gut.⁷⁴ Viral replication then takes place in the salivary glands and nervous system of the mosquito. In mosquito tissues, WNV is nonlytic and results in persistent infection for the lifetime of the vector.

Mosquitoes play an important role in transgenerational and trans-seasonal maintenance of the WNV enzootic cycle. Female *C. pipiens* mosquitoes can transmit WNV vertically to F1 progeny.^{63,212} In addition, WNV can survive the winter by overwintering in hibernating female mosquitoes, as documented with *C. pipiens*, which thereby serve as a source of WNV to initiate the enzootic cycle the following spring.¹⁵⁵

Although numerous mosquito species have been found to be infected with WNV, ornithophilic members in the *Culex* genus are the principal vectors for the transmission of WNV around the world. These include *Culex pipiens* and *Culex quinquefasciatus* in Europe, *Culex perexiguus* in North Africa and the Middle East, *Culex univittatus* in sub-Saharan Africa, *Culex tritaeniorhynchus* in south Asia, *Culex annulirostris* in Australia, and species of the *Culex vishnui* complex in India.¹¹³

Although WNV has been found in 59 of the 172 North American species of mosquitoes, only about a half-dozen are considered to be important vectors for transmission to humans.⁸⁹ As in other regions of the world, *Culex* spp. of mosquitoes are important vectors⁸⁹; *C. pipiens* (the northern house mosquito) and *C. quinquefasciatus* (the southern house mosquito) are considered to be the predominant vectors in the northeastern, southern, and southwestern United States, respectively. *Culex tarsalis* is a predominant vector west of the Mississippi River. *Culex nigripalpus* and *Culex salinarius* may be important vectors in regions where they are abundant. Last, *Culex restuans* also has been found to be a significant contributor to WNV-positive mosquito pools. Although arthropods can be infected with WNV, they are not thought to be important in transmission of WNV.

Birds are thought to be the principal amplifying hosts for WNV. Nearly 200 species of North American birds are susceptible to infection by WNV.¹¹³ However, only birds capable of sustaining high-titer viremia for significant periods are capable of infecting the mosquitoes that feed on them. In vivo experiments using *C. tarsalis* have shown that 74% to 100% of mosquitoes consuming blood meals containing 10^7 plaque-forming units (PFUs) per milliliter become infected. In contrast, 36% or fewer mosquitoes become infected after the consumption of blood containing 10^4 PFUs/mL.⁷⁵ As a point of comparison, on the basis of blood tested from viremic blood donors, the maximum viral load in human blood is approximately 10^3 PFUs/mL.⁸⁹ This finding indicates that humans fail to produce viremia titers of sufficient magnitude to infect mosquitoes. Most mammals also fail to have sufficient levels of viremia to permit transmission to mosquitoes.

Songbirds (Passeriformes), shorebirds (Charadriiformes), owls (Strigiformes), and falcons (Falconiformes) develop adequate viremia to infect mosquitoes feeding on them (pigeons and ducks do not). House finches, house sparrows, common grackles, and, in particular, corvids such as crows, magpies, and jays have been shown to be highly infectious to mosquitoes.^{89,113} In addition, they have a high mortality rate after acquiring infection with WNV. Die-offs of avian species serve as epidemiologic markers for WNV activity in the environment.^{79,149}

Unlike mammals, some amphibians appear to be capable of sustaining levels of viremia that potentially could be sufficient to infect mosquitoes and may serve as competent reservoirs for their infection. In the United States, alligators (*Alligator mississippiensis*) infected with WNV produced sufficient viral loads to infect mosquitoes.¹¹² Detection of WNV RNA in mosquitoes, alligators, and alligator-derived blood meals collected at alligator farms in Louisiana support the role of alligators as competent hosts for WNV amplification and transmission.²¹¹ In Russia, the marsh frog (*Rana ridibunda*) may be a host for WNV.^{89,115}

In areas where WNV traditionally has been endemic, seroprevalence studies document that most individuals acquire WNV infection during childhood. Such early acquisition of WNV infection results in large portions of the adult population with serologic evidence of immunity to WNV and may attenuate the occurrence of large outbreaks of WNV infection. Studies conducted in the 1950s in Egypt documented that a rapid rise in the presence of antibodies occurred in children 1 to 4 years of age such that by the time children were 4 years of age, 50% to 80% had neutralizing or complement-fixing antibodies to WNV.^{141,206} Similar patterns of acquisition of WNV-specific antibodies have been documented in the Sudan, Central Africa, and Nigeria.^{200,206} Interestingly, more recent studies conducted in Egypt indicate that the seroprevalence rates in children and young adults, although still high, may be decreasing.^{53,56} One can speculate that mosquito abatement programs and, possibly, changes in lifestyle have resulted in decreasing numbers of infections in children.

Seroepidemiologic studies conducted in areas where initial WNV has resulted in large outbreaks of West Nile fever and neuroinvasive disease document low seroprevalence rates among the general population.^{134,148,151,209} Investigation of the seroprevalence of WNV infection after an outbreak of WNV in Romania after the first major WNV epidemic in Europe found it to be 4.6%.²⁰⁹ After the initial North American outbreak of West Nile encephalitis in New York in 1999, the seroprevalence at the outbreak's epicenter was found to be approximately 2.6%.¹⁴⁸ Based on data derived from the screening of the United States blood supply, the estimated prevalence of past WNV infection among the United States population is approximately 1%.¹⁷¹ In areas where postepidemic seroprevalence has been conducted, it has been found to range from 1.9% to 14%—too low to protect against future large-scale outbreaks of WNV disease.^{47,151,171}

Multiple non-vector-borne modes of WNV transmission have been identified. Transfusion-associated transmission of WNV was reported for the first time in 2002, when 23 cases were confirmed.^{145,165} WNV virus infection has resulted from the transfusion of red blood cells, platelets, fresh frozen plasma, and granulocytes.^{42-44,142,144,165,170} Of the 32 cases, five (16%) occurred in children younger than 18 years.^{42,144,165} Three of the children had immunocompromising conditions (i.e., acute myeloid leukemia, rhabdomyosarcoma, stem cell transplant). The three children received platelet infusions and developed West Nile

meningoencephalitis; all survived. The sole adolescent was a victim of a motor vehicle collision and received a transfusion of red blood cells. This patient subsequently became an organ donor and was implicated in four cases of transplantation-associated transmission of WNV.^{36,100} A sole case of acquisition of WNV through granulocyte transfusion has been reported.¹⁴²

National screening of blood donations for the presence of WNV by nucleic acid amplification–based testing was initiated in June 2003. However, rare cases of transfusion-associated transmission have continued to occur. Since then, 13 probable or confirmed cases of transfusion-acquired WNV infection occurred through 2012 (none of which occurred in children); they most likely were attributable to donations containing very low levels of virus.^{40,44,46,129,142,144}

Transmission through organ transplantation has also been documented.^{36,41,43,100,157,179} However, no cases in pediatric transplant recipients have been reported.¹²⁹ From 2002 to 2013, six clusters of organ transplant-associated WNV transmission were reported to the CDC.¹² WNV infection developed in 12 of 16 transplant recipients, nine of whom developed encephalitis and four of whom died. The risk for acquiring West Nile neuroinvasive disease is approximately 40 times greater in organ transplant recipients than in the general population.¹¹⁶ Organ donations are not required to be screened by nucleic acid amplification for WNV infection, nor is it performed routinely.

Confirmed or suspected maternal-fetal and maternal-infant vertical transmission of WNV has been reported^{3,34,35,90,161} but seems to be an unusual occurrence.¹⁷² In a report of the outcomes of a small cohort of newborns whose mothers were infected with WNV during pregnancy, more than half occurring in the first and second trimesters, no infant was found to have evidence of WNV-specific immunoglobulin M (IgM) in cord blood.¹⁷² In the most rigorously documented case of maternal-infant transmission,^{3,34,90} confirmed maternal WNV infection occurred during the twenty-seventh week of gestation. The infant, delivered at 38 weeks of gestation, was found to have bilateral chorioretinitis, severe bilateral white-matter loss in the temporal and occipital lobes, and tissue destruction in a temporal lobe. The presence of WNV-specific IgM was confirmed in cord blood, infant serum, and cerebrospinal fluid (CSF), although the CSF contained red blood cells. Maternal serum also contained WNV-specific IgM at the time of birth. The WNV genome was detected in the umbilical cord tissue and placenta by reverse transcriptase polymerase chain reaction (RT-PCR). No WNV genome was detected in the infant's CSF.

Evaluation of 70 pregnancies reported to the CDC WNV pregnancy registry failed to identify any confirmed cases of congenital WNV infection.¹⁶¹ However, three infants who lacked evidence of anti-WNV IgM in cord blood or infant serum at the time of delivery subsequently were found to have serologic evidence of infection that may have been acquired congenitally. A breast-fed term infant, whose mother had onset of West Nile neuroinvasive disease 6 days before delivery, developed West Nile meningitis at 10 days of age. Another breast-fed infant, born to a woman with acute West Nile fever at the time of delivery, was noted to have a transient rash at birth. No serum or cord blood was available for testing. However, at 1 month of age, the infant was found to have WNV-specific IgM antibodies. In the final case, the infant's mother had a febrile illness 3 weeks before delivery. The infant appeared to be healthy at birth, but at 7 days of age developed seizures. Evaluation of the infant at 17 days of age found lissencephaly and West Nile encephalitis with WNV-specific IgM antibodies detectable in the CSF. Because two of the infants were breast-fed, the possibility exists that WNV was transmitted in that manner. In addition, in none of the cases could the possibility of mosquito-borne transmission of WNV be excluded conclusively. This report also failed to link WNV infection during pregnancy with an increased frequency of spontaneous abortion, premature birth, or low birth weight.

The outcome of children born to mothers with West Nile illness during pregnancy appears to be good.^{172,195} Two small studies have not identified developmental delays, neurologic defects, increased fetal loss, or an increased frequency of birth defects among infants born to women with confirmed WNV infection during pregnancy. However, it should be noted that both studies enrolled a small number of maternal-infant pairs. Larger studies are needed to confirm these findings.

WNV has been detected in the breast milk of infected women.^{35,161} At least one case of possible transmission of WNV associated with breastfeeding has been reported.^{35,88,161} The mother received packed red blood cell transfusions on the first 2 postpartum days. Ten days postpartum, the mother developed headache followed by fever. On evaluation, she was found to have CSF pleocytosis and the presence of WNV-specific IgM in the CSF. The infant was breast-fed for the first 17 days of life, and although the infant was clinically asymptomatic, a serum sample obtained at 25 days of age was found to have WNV-specific IgM. Because of the paucity of additional case reports, it appears that the risk for WNV transmission from mother to infant through breastfeeding is low. The current state of knowledge about transmission of WNV through breast milk does not warrant a change in breastfeeding recommendations.

Additional nontraditional modes of confirmed or possible transmission of WNV has been reported through laboratory exposure, animal autopsies, percutaneous injury, conjunctival inoculation, aerosol inhalation, and dialysis.^{37-39,67,83,213,214}

With the exceptions of Alaska and Hawaii, every state in the United States has reported human, mosquito, avian, or animal WNV. From 1999 to 2014, 41,762 cases of WNV infection were reported to the CDC (see Table 176B.1).⁴⁶ Neuroinvasive syndromes accounted for 18,810 cases (45%), and nonneuroinvasive syndromes were reported in 22,952 cases (55%). During the same period, 1765 deaths (4%) were reported.⁴⁶

Pediatric-specific epidemiologic and clinical data regarding WNV infections has become available but is most likely incomplete because of underreporting of cases.^{88-90,129} After an Ohio outbreak of WNV, the county-wide seroprevalence rate was found to be 1.9%. However, among children younger than 17 years, the seroprevalence rate was nearly 3.5 times higher: 6.4%.¹³⁴ From 2003 to 2012, 13,108 cases of West Nile neuroinvasive disease were reported to the CDC (see Table 176B.1).⁴⁶ Children accounted for 505 cases (4%). The median number of pediatric cases per year was 49 (range, 7–137).⁷⁰ For that period, the median annual incidence of West Nile neuroinvasive disease was 0.68 cases per 1 million children and ranged from 0.09 to 1.85 cases per 1 million children. By way of comparison, for the same period the median annual incidence for adults was eightfold higher. States in the North Central and Mountain regions had the highest annual incidence. The four states with the highest annual pediatric incidences were South Dakota (10.36 per 1 million children), Wyoming (5.91 per 1 million children), North Dakota (5.34 per 1 million children), and Nebraska (5.23 per 1 million children). Seven states accounted for greater than half of all reported cases: Texas (77 cases), California (49), Louisiana (34), Colorado (32), Arizona (29), Nebraska (24), and South Dakota (21). Boys accounted for 61% of cases.

The distribution of WNV syndromes among children has been difficult to define because of underreporting of pediatric cases of West Nile infection.⁸⁸ Lindsey and colleagues reported cases of West Nile infection in children from 1999 through 2007 and noted that 1478 (5%) occurred in children younger than 18 years.¹²⁹ It is the only large study that has reported on the percentage of pediatric infections that result in nonneuroinvasive (68%) versus neuroinvasive (30%) disease.¹²⁹ In that report the median age of children with West Nile fever in one report spanning a decade was 14 years (range, 1 day to 17 years).¹²⁹ Children accounted for 4% of all neuroinvasive cases of West Nile infection from 1999 to 2013.^{71,129} The median age of children with West Nile neuroinvasive disease was 12 years.^{71,129} Of the children with neuroinvasive disease, 50% had meningitis, 40% encephalitis, and 3% acute flaccid paralysis.⁷⁰ Half of those with acute flaccid paralysis also had meningitis or encephalitis.

Three deaths have been reported—a 1-month-old boy, a 14-year-old boy, and a 16-year-old girl. Two of the children who died of neuroinvasive disease had underlying medical conditions; one had an immunodeficiency and the other lissencephaly.^{90,129,159}

Available information indicates that WNV infection in children is typically mild, resulting in West Nile fever in more than two-thirds of children with symptomatic infection. The distribution of West Nile neuroinvasive disease in children indicates that the predominant West Nile neuroinvasive syndrome is meningitis, followed by encephalitis.

PATHOGENESIS

The pathogenesis of West Nile encephalitis has been explored in animal model systems. Subcutaneous inoculation of WNV is thought to result in WNV infection and replication in Langerhans dendritic cells.²⁷ Domain III of the WNV envelope (E) protein is believed to interact with DC-SIGN or DC-SIGNR to mediate cellular attachment. Under control of interleukin-1 β , activated Langerhans cells migrate to regional lymph nodes and result in a primary viremia that develops after the virus reaches the systemic circulation through the thoracic duct.²⁷ In mice, peak viremia occurs by the second day after infection and clears by the sixth day. Virus subsequently can be detected in spleen, brain, and spinal cord. Because of the simultaneous appearance of virus in the brain and spinal cord, a hematogenous route for the CNS infection has been postulated. In humans, WNV can be detected in the neurons of the cerebral cortex, thalamus, brainstem, basal ganglia, cerebellum, and spinal cord, primarily in the anterior horn. Similar locations have been seen in mice and hamsters. Infection of the neurons in these sites results in meningoencephalitis and acute flaccid paralysis. Several mechanisms have been postulated for the neuronal injury seen in WNV infection¹⁹⁴: viral injury to infected neurons through apoptosis, targeting of infected neurons by cytotoxic T lymphocytes, and neuronal death as a result of bystander injury. Cell death of WNV-infected neurons has been shown to be caspase-3 dependent.

The mechanism by which WNV gains access to the CNS is not fully understood. WNV binding to toll-like receptor-3 (TLR3) has been shown to result in TLR3 receptor–dependent inflammatory response with resultant production of tumor necrosis factor- α (TNF- α) and interleukin-6.²¹⁷ TNF- α may modulate the ability of WNV to invade the CNS, inducing breakdown of the blood-brain barrier. Macrophage migration inhibition factor, induced endothelial cell adhesion molecule-1 and matrix metalloproteinase-9 also have been shown to play roles in increased brain capillary epithelial permeability.^{6,55,216} Additional postulated mechanisms through which WNV may breach the blood-brain barrier include infection or passive transport through the choroid plexus epithelial cells or the endothelium, infection of olfactory neurons, transport within infected immune cells that traffic into the CNS (Trojan horse mechanism), and retrograde axonal transport in infected peripheral neurons.¹⁸⁵

Cessation of the viremia occurs by the sixth day in mice and is coincident with the appearance of type-specific antibody response. Viral clearance from all tissues is complete by 2 to 3 weeks after infection. Humoral immunity is essential to the recovery from WNV infection, as demonstrated by the uniform death of B-cell–deficient mice.⁶¹ B-cell–deficient mice could be protected from lethal infection by the passive transfer of serum from infected and immune wild-type mice. Mice deficient in CD4⁺ T cells exhibited prolonged detection of WNV in the CNS, lower WNV-specific levels of IgM and IgG, and uniform lethality, indicating that the principal protective role of these cells is to assist in antibody responses. $\gamma\delta$ T cells that secrete IFN- γ may control viral replication through direct antiviral mechanisms and contribute to adaptive immune responses.¹⁸⁵

Although clearance of WNV from the CNS and other tissues depends primarily on humoral immunity, cytotoxic T cells also play a role.^{126,210} Increased mortality rates in association with higher and sustained WNV loads in the CNS and spleen were observed in mice deficient in CD8⁺ T cells or class I major histocompatibility complex molecules.¹⁹³ In addition, control of WNV infection in the CNS requires IFN- α/β . IFN- α/β also may help increase the survival of neurons. Finally, chemokines such as CXCL10 and CCL5 and their ligands CXCR3 and CCR5 aid in the recruitment of CD4⁺ and CD8⁺ T cells and monocytes to the CNS.¹⁸⁵

CLINICAL MANIFESTATIONS

Most WNV infections in children and adults result in subclinical disease. In general, WNV infection in children more frequently results in asymptomatic infection or milder disease than that in adults.^{49,77,129,156,187,204} One report documented that children were 4.5 times more likely to become infected with WNV during an epidemic but 110 times less

likely to develop neuroinvasive disease.¹³⁴ In another, the estimated incidence of neuroinvasive disease was 1.4 per 100,000 children aged 5 to 17 years in contrast to 14.3 per 100,000 individuals aged 18 years or older.¹¹⁷ In adults, multiple reports have identified increasing age as the single most significant risk factor for the development of neuroinvasive disease, as well as adverse outcome.^{129,152,168} The incidence of severe neurologic disease is 10 times higher in individuals aged 50 to 59 years and 43 times higher in persons aged 80 years or older in contrast to those 20 years or younger. Chronic illnesses, such as hypertension, diabetes mellitus, cardiovascular disease, and alcohol abuse, also have been identified as risk factors for severe disease.^{22,152,156,168} These factors have not been linked to an increased risk for the development of severe disease in children.

In the early 1950s, therapeutic inoculation of WNV into patients with malignant neoplasms in advanced stages resulted in a high incidence of development of encephalitis among recipients and pointed to the role of immunosuppression as a risk factor for West Nile neuroinvasive disease.²⁰³ This finding was substantiated by the recognition that transplant recipients were 40 times more likely to develop West Nile neuroinvasive disease.¹¹⁶ Reports of West Nile neuroinvasive disease in immunocompromised children also are consistent with immunosuppression as a risk factor in this population.^{7,68,94,176,201} Reports also have indicated that the use of immunomodulating agents such as infliximab, rituximab, methotrexate, and fludarabine may predispose to the development of severe WNV infection.^{13,48,124,139}

Approximately 20% of infected adults develop West Nile fever. Because of the fever's mild nature, only about half of individuals with West Nile fever ever seek medical attention. WNV neuroinvasive syndromes (e.g., encephalitis, meningitis, meningoencephalitis, and acute flaccid paralysis) develop in less than 1% of adults (one in 140–320) infected with WNV.^{148,156,168,209} The occurrence of West Nile neuroinvasive disease in children is significantly less.^{117,134} In one study, it was calculated to occur in approximately one in 4200 infected children.¹³⁴

The incubation period of WNV infection ranges from 2 to 14 days but usually is 2 to 6 days.^{28,77,113,136} Viremia may be present from approximately 2 days before to approximately 4 days after the onset of the illness.⁷⁶ In immunosuppressed individuals, incubation periods up to 3 weeks have been reported and may exhibit prolonged periods of viremia.^{100,165}

In children^{52,68,77,90,98,136,223} and adults, West Nile fever is an influenza-like febrile illness characterized by an abrupt onset of fever that typically ranges from 38°C to 40°C (100.4°F–104°F). It is accompanied by fatigue, malaise, anorexia, headache, myalgias, and weakness.^{28,77,136,168,218} Ocular pain on eye movement has been reported.^{77,136} A diffuse, nonpruritic, macular, papular, maculopapular, or morbilliform exanthem and diffuse lymphadenopathy also may be seen. On occasion, it has been described as petechial.^{24,52,181} The rash spares the palms and soles and generally involves the chest, back, and arms.¹⁸¹ The exanthem may be present more frequently in children than in adults, regardless of the WNV syndrome, occurring in 50%.^{25,52,181} The exanthem generally is present for less than a week. Neck pain and photosensitivity often are reported. Gastrointestinal complaints such as nausea, vomiting, abdominal pain, and diarrhea may occur. Sore throat and cough also have been reported. The illness generally is short-lived, lasting only 3 to 6 days.^{77,98,136} Convalescence, however, may take many weeks and is characterized by fatigue.^{77,136,218}

Other nonneurologic WNV syndromes that have been reported in adults include cardiac dysrhythmias, myocarditis, pancreatitis, hepatitis, rhabdomyolysis, myositis, and orchitis.^{9,24,91,93,140,145,156,223} Myocarditis and hepatitis have been reported in children with West Nile infection.

Although cases of West Nile neuroinvasive disease have been reported in children,* most of the information about these clinical syndromes has been derived from reports that have involved predominantly adults.† However, on the basis of a limited number of pediatric cases and series, the clinical presentation in children appears to parallel that of adults.¹⁸⁷ Although discussion of each of the neuroinvasive syndromes individually

(i.e., meningitis, encephalitis, and acute flaccid paralysis) is convenient, one should recognize that patients may have components of each in their clinical presentation. Finally, the clinical findings in West Nile neuroinvasive disease in children and adults are not sufficiently distinct to distinguish them from those of other viral meningitides or encephalitides.

In adults, the onset of West Nile meningitis tends to be abrupt, with fever, headache, and neck stiffness and meningeal signs (Kernig and Brudzinski signs).* Photophobia and phonophobia may be present. The headache pain may be severe enough to warrant the use of opioid analgesics. Weakness frequently is reported.^{52,68} Additional associated symptoms may include those seen with West Nile fever: gastrointestinal and respiratory symptoms (i.e., nausea, vomiting, diarrhea, sore throat, and cough), rash, and lymphadenopathy. Dyskinesias in the form of tremors, myoclonus, or parkinsonism also may occur.

The reported clinical findings of West Nile encephalitis in children† are similar to those described in adults.^{22,28,49,156,168,187} The onset of frank encephalitis may be preceded by a brief period, or prodrome, of fever, headache, rash, and malaise consistent with West Nile fever. In some cases, the appearance of fever is coincident with the onset of mental status changes. The mental status changes may range from a mild confusional state to severe encephalopathy and coma. Generalized weakness is a common component of the clinical spectrum of encephalitis. Paresis or palsies may be present. Ataxia, dysmetria, tremors, myoclonus, and parkinsonism may be seen.^{52,146,158} Signs of bulbar dysfunction, such as dysarthria, dysphagia, and respiratory failure, have been reported. If a component of meningitis is present (i.e., meningoencephalitis), signs and symptoms described previously for meningitis also may be present. Seizures have been reported in children^{7,30,68,159,180,201} and may be focal with associated neurologic signs similar to those of herpes simplex virus encephalitis.^{180,215}

Acute flaccid paralysis in association with WNV infection was reported first in 1979⁷⁰ and may occur in the absence of meningitis or encephalitis. Several reports of acute flaccid paralysis, alone or in association with encephalitis, developing after the occurrence of WNV infection in children have been published.^{24,68,80,92,183,198,207}

The onset of the paralysis occurs early in the illness, usually within the first 72 hours.¹⁸⁹ Pain or paresthesia in the affected limb preceding the onset of weakness is reported in most cases.^{80,189} Patients exhibit asymmetric weakness, hypotonia, and absent or diminished deep tendon reflexes. Pain or sensory function in the affected limbs remains intact.^{9,102,110,125,183,189} However, at least one report has documented electrophysiologic evidence of sensory fiber loss in association with severe spinal cord involvement.⁶⁴ It is postulated that this finding could be explained by damage to neurons in the dorsal root ganglia. Tremor, myoclonus, and parkinsonism are common findings.^{190,191} In severe cases, changes in bowel and bladder function or quadriplegia may occur. Involvement of the brainstem motor nuclei of the vagus and glossopharyngeal nerves can result in dysphagia, dysarthria, and acute respiratory failure requiring assisted mechanical ventilation.²⁴ Patients with dysphagia and dysarthria are at greater risk for the development of respiratory failure.¹⁸⁹

Ocular manifestations of WNV infection include chorioretinitis/retinitis, vitritis, and uveitis.^{10,93,187} Chorioretinitis has been described in congenital and postnatal WNV infections^{3,10,187} and may be more common than is realized.⁹¹ Postnatal cases of West Nile chorioretinitis have been reported solely in adults. A recent study found that 24% of adults with a history of WNV infection had evidence of WNV-associated retinopathy. The finding of was even more frequently observed in those who presented with encephalitis, in whom it approached 50%.⁸⁶

In the sole reported case of congenital WNV infection, the infant had a large chorioretinal scar involving the retina of the right eye. Mild chorioretinal scarring was observed in the far temporal periphery.^{3,10} Vitritis also has been reported in children and can lead to blurring and loss of vision.²²³

Other rarely reported neurologic manifestations of West Nile neuroinvasive disease in adults include optic neuritis, myelitis, Guillain-Barré syndrome,² and polyradiculitis.¹⁶⁴

Recently, the possibility of long-term persistence of West Nile virus infection has been raised.¹⁵⁴ WNV genome was detected by RT-PCR in the urine in 20% of a cohort of patients with neuroinvasive disease 1.6 to 6.7 years after initial infection. All patients reported persistence of neurologic symptoms or signs. This finding is consistent with findings in the hamster model WNV infection and suggests ongoing replication in renal tissue. However, attempts to isolate virus from the urine were unsuccessful. In addition, a higher than expected prevalence of chronic kidney disease associated with proteinuria and hematuria has been documented in a cohort of patients with a history of neuroinvasive WNV.¹⁶⁰

OUTCOME

Based on cases reported to the CDC from 1999 to 2012, the mortality rate in children is less than 1%.^{70,129} Although reports of death in children as a result of WNV infection are rare,^{32,73,88,94} WNV outbreaks associated with significant pediatric mortality rates (12.9%) have been documented.^{60,122} From 2002 to 2011, the case-fatality rates in adults ranged from 2.6% to 6.8% (mean, 4.6%).³⁷ Hospitalized persons 75 years or older are nine times more likely to die than are younger patients. Other reported independent risk factors for death in adults are change in level of consciousness and anemia at presentation.⁴⁹ In addition to early mortality, delayed mortality, occurring years after infection, has been reported.¹³¹

Although complete recovery from West Nile fever is expected, it may take several weeks before children and adults return to preillness levels of health.^{77,164} Watson and colleagues²¹⁹ found that the median time to complete recovery in adults was 60 days. Postillness fatigue was reported in 98%, and the median duration of fatigue was 36 days. Sixty-one percent of patients reported muscle weakness of a median duration of 28 days. Other symptoms that persisted for longer than 7 days were reported in more than half of the subjects and included headache, muscle pain and aches, difficulty concentrating, joint pain and aches, and sensitivity to light. Of those who worked or attended school, nearly 60% reported absenteeism of more than 7 days.

Neurologic outcome of children after West Nile neuroinvasive disease has not been assessed systematically. The published case reports of West Nile neuroinvasive disease in children are most likely biased by the disease severity or outcome and limited by a lack of long-term follow-up of patients. As such, reliable information about the outcome of West Nile encephalitis and acute flaccid paralysis is lacking. However, on the basis of the review of 47 reported cases of West Nile neuroinvasive disease in children and adolescents for whom clinical and outcome information was provided,^{*} recovery from meningitis appears to be complete in children ($n = 20$). Among cases of encephalitis, meningoencephalitis, and acute flaccid paralysis ($n = 27$), approximately 50% of children were reported to have neurologic sequelae at the time of last medical encounter or at the time the report was submitted. The reported sequelae among children include seizures, weakness, paralysis, gait disturbances, motor difficulties, language and speech deficits, dysphagia, behavior problems, cognitive deficits, mental retardation, difficulty concentrating, difficulties with memory and comprehension, facial palsy, hypertonicity, and persistent vegetative state.^{7,24,68,92,96,159,201,215,220,223}

Children and adults recovering from West Nile acute flaccid paralysis exhibited persistent associated neurologic signs, poor physical recovery, and atrophy of affected limbs.^{103,190} Although the degree of initial paralysis was not correlated with long-term outcome in an early report,²⁹ a more recent publication indicates that the degree of initial paralysis may be an important indicator of long-term outcome.¹⁹⁰ The greatest recovery in strength occurred during the first 4 months after paralysis.¹⁹⁰

LABORATORY FINDINGS

As is the case with the clinical findings of WNV infections, routine laboratory studies are nonspecific and do not provide conclusive evidence

about the etiologic agent. Similar to those in adults, hematologic findings in children include leukocytosis, leukopenia, normal total white cell count, and lymphopenia.^{7,52,59,117,180,201,215,220,223} Pediatric and adult cases of encephalitis hyponatremia have been reported.^{24,49,221} Elevations of transaminases and creatine kinase may be seen in children with hepatitis and myositis.^{24,223}

Cytochemical evaluation of the CSF generally reveals an abnormal white cell count and protein concentration.^{*} A predominantly lymphocytic pleocytosis with, generally, fewer than 200 cells/mm³ is a frequent finding. Cell counts of more than 2000 cells/mm³ have been reported. Early in the infection, the CSF may show a polymorphonuclear cellular predominance that later shifts to a lymphocytic pleocytosis.⁵⁴ A mildly increased protein concentration of less than 100 mg/dL generally is seen. However, considerable variation in CSF protein concentration has been reported in patients with West Nile encephalitis. A normal CSF glucose concentration generally is observed.

ELECTRODIAGNOSTIC STUDIES

Electrodiagnostic study findings are abnormal in most patients with West Nile encephalitis.[†] Electroencephalographic abnormalities have included diffuse irregular slow waves, focal sharp waves, and subclinical electrographic seizures. An anterior preponderance of slow waves has been suggested as characteristic of West Nile encephalitis.⁷² Reports of focal electroencephalographic findings suggestive of herpes simplex virus encephalitis have been reported in children.^{180,215}

In patients with acute flaccid paralysis, electromyography, and nerve conduction studies document normal nerve conduction velocities, normal or reduced compound muscle action potentials, and normal sensory nerve action potentials consistent with anterior horn cell disease.^{4,33,64,80,92,110,123,125,156,191,192} Electrophysiologic documentation of severe loss of sensory fibers exists.⁶⁴

NEUROIMAGING

Magnetic resonance imaging (MRI) is more sensitive than computed tomography in identifying CNS abnormalities in patients with West Nile neuroinvasive disease. However, even in cases of severe encephalopathy, MRI may fail to find any abnormalities.²⁵ Reported MRI findings in cases of West Nile neuroinvasive disease appear as hyperintense signal on T2-weighted and fluid-attenuated inversion recovery images and are nonenhancing and of normal intensity on T1 weighting.^{102,169} In children and adults, lesions tend to be seen more frequently in the deep gray matter of the brain and, in particular, the basal ganglia, posterior thalami, and substantia nigra.^{7,23,25,68,156,168,191,221} Leptomeningeal and paraventricular enhancement may also be seen.^{24,176} Focal abnormalities occasionally may be seen, as noted in two cases of children with encephalitis in whom focal enhancement of the right temporal lobe was noted.^{59,69,215}

In cases of acute flaccid paralysis, abnormal T2-weighted signals may be seen in the spinal cord gray matter.^{4,92,102,125} In a case of a child with acute flaccid paralysis, MRI of the spine documented edema of the anterior horns of the cervical spinal cord.⁹²

VIRAL CULTURE AND NUCLEIC ACID AMPLIFICATION DETECTION OF WEST NILE VIRUS

Multiple reports have documented that WNV can be detected from the blood and brain of infected individuals by use of mouse inoculation or cell culture.^{19,73,76,77,83,97,141,200,203} However, this approach to establishing the diagnosis of WNV infections is of limited utility because of lack of sensitivity resulting from the brevity of the viremia, which begins approximately 2 days before and persists until approximately 4 days after the onset of the illness.^{77,168,203} In addition, because of the potential

risk to laboratory personnel, attempts to isolate WNV from human specimens should be undertaken only in an appropriate biocontainment environment (i.e., biosafety level 3 containment).

Numerous nucleic acid amplification assays (i.e., RT-PCR, RT loop-mediated isothermal amplification) for the detection of WNV have been developed.^{118,163} Diagnosis of acute WNV infections by nucleic acid amplification–based detection of WNV genome from blood and CSF clinical specimens also has limitations because of the short period of viremia.^{118,168} Although genome could be detected in all brain tissue specimens tested, only 57% of CSF specimens and 14% of sera from patients with serologically confirmed infection were positive by a real-time RT-PCR assay.¹¹⁸ Nucleic acid amplification–based detection of WNV has not been proved to be useful for the clinical diagnosis of WNV infections, but it has been extremely valuable in the screening and detection of asymptomatic viremia in blood donors.¹⁴⁴

DETECTION OF WEST NILE VIRUS-SPECIFIC ANTIBODIES

Given the limitations of virologic and nucleic acid amplification–based diagnostic assays, detection of virus-specific antibodies forms the mainstay for establishing the diagnosis of WNV infections. In cases of neuroinvasive disease, the presence of WNV-specific IgM in serum and CSF increases by 10% per day the first week of illness such that it is usually detectable in 70% to 80% of patients by 8 days after onset of illness.^{91,205} Interestingly, WNV-specific IgM may persist for long periods in serum and CSF of acutely infected individuals.¹⁷⁰ Fifty-eight percent of serum samples obtained approximately 500 or more days from onset of West Nile encephalitis were in the positive or equivocal range for WNV-specific IgM.¹⁸² In a more recent study, serum anti-WNV IgM was detected in 23% of individuals up to 8 years after acute infection.¹⁵⁴ Similarly, WNV-specific IgM has been detected in the CSF for up to 199 days after onset of illness.¹⁰⁶

The interflavivirus cross-reactivity of anti-flaviviral IgG antibodies is well recognized. Traditionally, confirmation of anti-flaviviral antibody specificity requires the use of a functional antibody assay such as the plaque reduction neutralization test.¹²⁸ Although multiple reports have documented greater specificity of anti-flaviviral IgM antibodies and, in particular, those of WNV-specific IgM antibodies,^{137,138,205} cross-reactions may still occur. On the basis of cross-reactivity with related flaviviruses (i.e., Japanese encephalitis virus and St. Louis encephalitis virus), an algorithm for the use of CDC-developed IgM capture enzyme-linked immunosorbent assay (MAC-ELISA) has been developed to differentiate human WNV and St. Louis encephalitis virus infections.¹³⁸ This algorithm has not been validated for commercial MAC-ELISA kits. In the absence of use of the CDC MAC-ELISA, confirmation of WNV infection may require documentation of presence of WNV functional (i.e., neutralizing or hemagglutination inhibition) antibodies.

The diagnosis of WNV infection currently relies on the detection of WNV-specific antibodies in CSF or paired serum samples.^{91,187} The MAC-ELISA is the most sensitive and commonly used diagnostic assay. It is capable of detecting IgM antibodies in CSF 3 to 5 days into the clinical illness and 3 or more days earlier than detectable serum antibody.²⁰⁵ The finding of WNV-specific IgM in the CSF of a child with a clinically compatible CNS syndrome generally is considered diagnostic of acute neuroinvasive infection. However, as discussed previously, persistence of WNV-specific IgM antibodies for as long as 199 days in the CSF has been reported.¹⁰⁶

Detection of WNV-specific IgM antibodies in serum from a single specimen may not be diagnostic of WNV infection because of its prolonged persistence in serum.^{153,182,187} When only serum is used for establishing a diagnosis, a second serum sample should be obtained at least 2 weeks later to document a fourfold increase in specific antibody titers with use of a functional assay such as neutralization or hemagglutination inhibition.¹⁹² Serologic cross-reactions among St. Louis encephalitis virus, WNV, and Powassan virus may occur²⁰⁸ and can confound the diagnosis in regions where multiple viruses are endemic. Serologic testing ideally should include a battery of region-specific

arboviral antigens. Confirmatory assays, such as viral neutralization with the plaque reduction neutralization test, are available from the CDC Division of Vector-Borne Infectious Diseases, but only a limited number of commercial diagnostic laboratories and state public health laboratories have the capacity to perform the test.¹⁰¹ The sensitivities and specificities of commercially available tests for the detection of WNV-specific antibodies may vary. An attenuated immune response may occur in immunocompromised hosts and result in a delayed antibody response.¹⁶⁵ Therefore serologic assays should be interpreted with caution in this population, and adjuncts such as nucleic acid amplification should be used to establish the diagnosis.

NEUROPATHOLOGY

Gross examination of the brain, spinal cord, and meninges generally is unremarkable but may demonstrate evidence of edema. In severe cases, the leptomeninges may show a perivascular monocyctic infiltrate on microscopic examination.²⁰⁹ Although the parenchymal findings of West Nile encephalitis can be seen distributed in nearly all areas of the CNS, the deep nuclei (i.e., thalamus, caudate, and lentiform nuclei), the substantia nigra, and other regions of the brainstem (in particular the pons and medulla), cerebellum, and spinal cord^{28,78,107,156,162,184,209} may be more severely involved.

The CNS pathologic changes are the result of direct viral replication in neuronal and, less so, glial cells as well as the cytotoxic immune response to infected cells.^{28,126} WNV demonstrates a penchant for infecting neurons. Viral antigen is detectable in neurons of fatal cases.^{9,28,78,201} Neuronal pyknosis or neuronophagia is seen. Features in fatal cases of West Nile encephalitis include perivascular mononuclear inflammatory infiltrates composed predominantly of B lymphocytes, CD8⁺ T-lymphocyte–dominant microglial nodules in the brain parenchyma, and focal mononuclear inflammation along the cranial nerve roots of the medulla.^{9,12,23,69,78,111,156,184} In the cerebellum, the Purkinje cell layer demonstrates inflammation, neuronal loss, and gliosis.

In cases of acute flaccid paralysis, WNV demonstrates a penchant for infection of the anterior motor neurons. The anterior horns of cervical and lumbar regions are the most severely involved areas.^{23,69,78} Evidence of neuronophagia, neuronal loss, and perivascular monocyctic infiltrates has been found.²³ Loss of ganglionic neurons, nodules of Nageotte, and perivascular lymphocytic aggregates have been seen in the dorsal roots and sympathetic ganglia.^{22,69}

TREATMENT

Treatment of West Nile fever and neuroinvasive syndromes is primarily supportive. In the case of West Nile encephalitis and meningoencephalitis, close monitoring of respiratory status is essential. Patients with severe muscle weakness, paralysis, dysphagia, or dysarthria may require mechanical ventilation.

No effective antiviral therapy currently is available for the treatment of WNV syndromes. Ribavirin, a broadly active antiviral, has been shown to be active against WNV in vitro and may have as its mechanism of action error-prone replication.^{58,104} In the sole pediatric case report, ribavirin was administered orally to a 14-year-old with Hodgkin lymphoma and West Nile meningoencephalitis who recovered completely.²⁰⁴ Although encouraging, a report of ribavirin in an unblinded, uncontrolled manner for the treatment of WNV infection in 37 patients during an outbreak in Israel in 2000⁴⁹ associated its use with a higher mortality rate. Bivariate analysis indicated that its use was associated with a greater likelihood of death (odds ratio, 6.7; 95% confidence interval, 3.0–15.2). Because this was an uncontrolled trial, selection bias for its use in more severely ill patients cannot be excluded. However, in a hamster model of WNV infection, ribavirin treatment alone increased the mortality rate.¹⁴⁷ These reports indicate that the use of ribavirin for the treatment of WNV infections appears to be unwarranted and unsupported at this time.

In cell culture, animal models, and a pilot study, IFN- α has been shown to be beneficial against some flaviviruses.^{147,175} Although anecdotal reports^{105,186} in humans suggest that the use of interferon- α 2b may

improve recovery from West Nile encephalitis, an open-label, nonblinded trial did not indicate benefit.¹⁸⁷

Anecdotal reports of the use of an intravenous immunoglobulin preparation containing a high neutralizing titer of anti-WNV antibodies (Omr-IgG-am) for the treatment of West Nile neuroinvasive disease in adults^{17,81,82,124,133,179,188} and children^{24,94} have been published. The limited information suggests a benefit from their use in some cases. Case reports and a case series suggest that use of hyperimmune gammaglobulin as early as possible in the course of encephalitis and acute flaccid paralysis may be associated with better outcome.^{133,207}

A report of the treatment of macular edema associated with WNV chorioretinitis with bevacizumab has been published.¹ Bevacizumab is a humanized monoclonal antibody that inhibits angiogenesis by inhibition of vascular endothelial growth factor A.

In a phase I study a monoclonal antibody to WNV was demonstrated to have mild adverse effects and be well tolerated in healthy adults.¹⁶ However, further clinical trials have not been reported.

PREVENTION

Prevention of WNV infections requires both community-based public health programs and personal measures. Mosquito abatement through elimination of mosquito breeding sites, use of larvicides to breeding areas, and application of pesticides targeted to adult mosquitoes are approaches used to reduce the abundance of mosquitoes in the environment.

The use and maintenance of door and window screens as physical barriers to prevent mosquitoes gaining access to homes can limit exposure to mosquitoes. Similarly, during engagement in outdoor activities where mosquitoes are prevalent, the use of mosquito netting in sleeping quarters also may decrease exposure to mosquito bites. Individuals should use insect repellent on skin and clothes when exposure to mosquitoes is probable or possible. Repellents such as N,N-diethyl-meta-toluamide (DEET), picaridin, and lemon eucalyptus oil have been shown to be effective and provide long-lasting protection.¹¹ Permethrin and DEET have been shown to be effective protection against mosquitoes when applied to clothing.

Finally, avoidance of environments where mosquitoes are found to be in high concentrations and avoidance of outdoor activities during dusk and dawn, when mosquito activity is the highest, should be encouraged. Efforts to prevent transmission of WNV through blood transfusions have led to the use of nucleic acid amplification–based tests for the screening of donated blood. At this time, screening of organ donors for the possible presence of West Nile infection has not been recommended.¹⁰⁸

The development of WNV vaccines for use in humans has taken various approaches: live, attenuated virus, inactivated virus, viral subunits, DNA, and chimeric/recombinant viruses.⁵ To date, eight phase I or II vaccine trials have been completed using a DNA vaccine containing the prM and E coding sequences (NIAID), soluble E protein lacking the C-terminal transmembrane domains (Hawaii Biotech), and two chimeric vaccines derived from dengue 4 virus (NIAID) and yellow fever virus (Sanofi-Aventis).

Only the latter has progressed to phase II trials. An infectious clone of yellow fever 17D virus was used as the background for the homologous exchange and insertion of the WNV prM and E genes.¹⁴³ The WNV E gene was mutated at three sites to reduce neurovirulence.⁸ A phase I chimeric WNV–yellow fever virus vaccine was well tolerated, and the incidences of adverse events were similar in both the vaccine and the placebo groups.^{143,197} A transient viremia was observed in 93% of recipients of chimeric vaccine. High levels of neutralizing antibodies were detected in 100% of the recipients. CD8⁺ responses were induced in 93% to 100% of vaccine recipients. The phase II study^{14,20} used a small plaque variant of the vaccine strain, which exhibited reduced viremia in a hamster model. It contained an additional amino acid mutation in the membrane protein. In part one of the study a short-lived viremia was observed but was lower than that seen in the phase I study, regardless of dose of given. Dose-ranging studies demonstrated that more than 96% of all vaccine recipients developed neutralizing antibodies. The highest dose (3.7×10^5 PFUs) was used for the second part of the

study. The mean peak titer of the viremia and its duration were greater in the cohort 65 years and older than in the 41- to 64-year-old cohort. Older patients exhibited higher neutralizing titers. Both cohorts had detectable neutralizing antibodies at 12 months and were higher in the 65 years and older cohort.

176C ■ Yellow Fever

Duane J. Gubler • Gail J. Harrison

FIGURE 176C.1 Geographic distribution of yellow fever in Africa and the Americas.

Yellow fever is a mosquito-borne viral disease of humans and lower primates that occurs naturally in tropical Africa and the Americas (Fig. 176C.1). Epidemics, which can occur in both urban and rural areas, often are associated with severe hemorrhagic disease and high fatality rates. It is considered a reemerging disease, with increased incidence documented since the 1980s.² Globally, yellow fever virus infects more than 200,000 people every year and causes approximately 30,000 deaths annually.

HISTORY

Yellow fever was described as a disease entity first in 1648 in the Yucatan, Mexico. It apparently was part of a larger regional epidemic that affected the Caribbean islands and Central America from Barbados to Mexico from 1647 to 1649.^{22,23} Although it was first described in the Americas, yellow fever virus, along with its principal urban epidemic mosquito vector, *Aedes aegypti*, most likely originated in Africa and was introduced to the New World by the slave trade. During the 17th, 18th, 19th, and early 20th centuries, epidemic yellow fever was a major public health problem in the Western Hemisphere. Large epidemics occurred in tropical America, as well as in the United States (as far north as Boston) and Europe (as far north as England).³³ Epidemics occurred primarily in port cities as a result of spread by sailing vessels and commerce.

After transmission by mosquitoes was documented by Reed and the Yellow Fever Commission in Cuba,³⁰ major efforts were undertaken to keep the disease in check by mosquito control. The first yellow fever virus was isolated in 1927 from a patient in Ghana, West Africa. By 1938, an effective live, attenuated virus vaccine had been developed. Yellow fever was controlled in the Americas by eradication of the mosquito vector of urban disease, *A. aegypti*, from most Central and South American countries. In Francophone countries of West Africa, yellow fever was controlled by mass vaccination programs. The result was the disappearance of major urban epidemics of yellow fever in both Africa and the Americas during the 1950s, 1960s, and 1970s. In the mid-1980s, however, the urban form of disease reemerged in West Africa, with major epidemics in Nigeria and increased transmission in other countries.²² Kenya experienced its first epidemic in history in 1993. Yellow fever outbreaks continue to occur in Africa. For example, Uganda experienced its largest yellow fever outbreak in 2010–11, related to occupational activities of males working in and around forests.³⁷ In 2015 Angola experienced a yellow fever outbreak; and 2016, the Democratic Republic of Congo Ministry of Health declared a yellow fever outbreak.²⁹ Previously, yellow fever was not seen in Asia. During the Angola outbreak, 11 unvaccinated Chinese workers were infected in Angola and imported yellow fever to China in 2016. At least one of

these workers died.⁵ This recent importation of yellow fever to China from unvaccinated workers and travelers exposed a low vaccination rate in Chinese travelers and workers in Angola and also exposed a potential threat of yellow fever spread to Asia.^{36,40} Imported cases of severe, fatal yellow fever have also been reported from other areas of the world, such as Europe (Germany and Belgium).¹ In the Americas, *A. aegypti* has reinfested most Central and South American countries from which it had been eradicated, and urban centers of the American tropics are at their highest risk for epidemic urban yellow fever in more than 60 years.¹³ Thus the disease continues to be an important public health problem in both Africa and the Americas. Yellow fever transmission has never been recognized in Asia or the Pacific, but the recent importation of yellow fever into China from unvaccinated travelers returning from an area with a yellow fever outbreak makes this occurrence a distinct possibility in the future.^{36,40}

ETIOLOGIC AGENT

Yellow fever is caused by the yellow fever virus, the prototype of the genus *Flavivirus*, family *Flaviviridae*. The genus *Flavivirus* contains 53 viruses, which are small (40–50 nm in diameter), spherical, and enveloped, with single-stranded RNA approximately 11 kilobases in length.⁹ The genome produces 10 proteins but has complex host interaction. Many of the flaviviruses are very closely related antigenically, which has resulted in extensive cross-reactivity in most serologic tests, so a laboratory diagnosis is difficult to make. Yellow fever virus has seven genotypes that are geographically separated, and outbreaks of disease are often associated with specific genotypes.² The virus is part of an antigenic complex that is different from other members of the family *Flaviviridae*.¹⁴

EPIDEMIOLOGY

Yellow fever viruses are maintained in natural zoonotic cycles involving lower primates and canopy-dwelling mosquitoes that breed in tree holes in the rain forests of both Africa and the Americas, called the *jungle* or *sylvatic cycle* of yellow fever.^{22,24,33} Humans become involved accidentally when they encroach on this forest cycle. Humans thus infected may transport the virus back to a village or city during the incubation period of 2 to 14 days. If infected persons are fed on by urban *A. aegypti*, the virus then can be transmitted to other humans by mosquito bite after an extrinsic incubation of 8 to 10 days. Major urban epidemics are transmitted by this highly domesticated mosquito, which lives in close association with humans in most tropical cities of the world.^{2,13}

Yellow fever occurs throughout much of sub-Saharan Africa and tropical America in the sylvatic cycle (see Fig. 176C.1). In Africa, cercopithecoid and celobid monkeys are the main vertebrate hosts; infection rarely causes illness and death in these species. Year-round enzootic transmission by *Aedes africanus* occurs in the rain forests. In wet savanna areas bordering the rain forests of western and central Africa, transmission increases during the rainy season and decreases during the dry season. *Aedes furcifer*, *A. africanus*, and *Aedes leuteocephalus* are the main mosquito vectors in this zone of emergence, and the virus is transmitted from monkey to monkey, monkey to human, and human to human. In the dry savanna zones, yellow fever activity is intermittent and takes place mainly during the rainy season, but it also occurs in major epidemics in urban areas, where stored water provides the ideal larval habitat for *A. aegypti*. In East Africa, *Aedes simpsoni* (*Aedes bromeliae*) provides the link between the *A. africanus* sylvatic cycle and humans in areas bordering gallery forests.

In tropical America, howler, spider, squirrel, owl, capuchin, and woolly monkeys all act as vertebrate hosts for yellow fever virus. Mosquitoes of the genus *Haemagogus* are the principal vectors in tropical American rain forests, where they feed in the canopy as well as at ground level. Other mosquito species, such as *Sabethes chloropterus*, *Aedes*

leucocelaenus, and *Aedes fulvus*, may play secondary roles. Although most cases of yellow fever have been reported from Bolivia, Brazil, Venezuela, and Peru in recent years, the enzootic zone probably includes the rain forests of at least 10 countries (i.e., Colombia, Ecuador, Peru, Bolivia, Brazil, Venezuela, Guyana, Suriname, French Guiana, and Trinidad⁴¹) and involves “wandering” enzootic transmission among the monkey populations. The humans involved are mainly adult men who work in the forest.

Vertical transmission of yellow fever virus from an infected female mosquito through the eggs to her offspring plays an important role in survival and maintenance of yellow fever virus in enzootic cycles and has been demonstrated in nature in West Africa by isolation of the virus from male *A. fuscifer* mosquitoes. Experimentally, *Haemagogus* and *A. aegypti* mosquitoes have been shown to be capable of vertical transmission. This mechanism is thought to be of major importance in survival of the virus during prolonged dry periods in both enzootic regions.

Urban epidemics of yellow fever have reappeared in West Africa in the past 17 years.²⁸ Unfortunately, surveillance is very poor, and the actual number of cases reported is thought to be grossly underestimated. For example, in Nigeria in 1986 and 1987, the numbers of reported cases and deaths during epidemics were 2612 and 973, respectively. Seroepidemiologic studies, however, estimated that the actual numbers of cases and deaths were 130,000 and 29,000, respectively.²⁸

In the Americas, the last urban yellow fever epidemic occurred in 1942. Reinvasion of American tropical urban centers by *A. aegypti*, however, has placed more than 300 million susceptible individuals at risk. As might be expected, urban transmission has been reported recently. In 1998, urban transmission of yellow fever was documented in Santa Cruz, Bolivia.³⁵ Although not comprising a large number of cases, this outbreak underscores the high risk that many tropical urban centers have at the beginning of the 21st century. In addition, six fatal cases of yellow fever in travelers who visited South America (four cases) or Africa (two cases) in recent years have been confirmed. Three of these cases were US citizens, and three were European. Why contemporary yellow fever epidemics have not occurred in the Americas, despite the high risk, is not known. The dramatic increase in transmission of dengue in urban centers of the American tropics in recent years possibly has resulted in a high prevalence of heterotypic flavivirus antibody that protects against severe yellow fever clinical illness. Another possibility is that the enzootic virus strains are not well adapted to urban transmission by *A. aegypti*.

Epidemic yellow fever has never been reported in Asia or the Pacific, although imported yellow fever from unvaccinated travelers recently has occurred in 2016.^{36,40} The reason is not known, but both variation in mosquito vector competence and partial protection by heterotypic flavivirus antibody have been suggested as reasons that this virus has never become established in that part of the world. If urban epidemics do occur in the American tropics, however, the virus is expected to move very quickly to this and other permissive areas where urban *A. aegypti* mosquitoes are found; this movement of yellow fever virus undoubtedly would cause a major international public health emergency.

CLINICAL MANIFESTATIONS

Infection with yellow fever virus causes a spectrum of illness ranging from inapparent infection to severe yellow fever with the classic triad of jaundice, hemorrhage, and albuminuria, which is associated with a high case-fatality rate. Most yellow fever infections are manifested clinically as a mild to severe viral syndrome without symptoms of intoxication; 10% to 20% of infections may result in classic yellow fever.^{21,24,25}

The incubation period may be as long as 13 days but generally is 3 to 6 days.²⁴ The onset of illness is abrupt, with fever, headache, backache, myalgia, nausea, and other nonspecific signs and symptoms. In mild cases, the illness will last for several days, after which recovery is uneventful and complete. In severe cases, prostration occurs commonly, and examination reveals congestion of the skin, conjunctivae, and mucous membranes. The pulse rate usually increases early in the illness, and

blood pressure is normal. Leukopenia is a frequent finding, and mild albuminuria may be noted. The temperature generally ranges between 38.5°C and 40°C (101.3°C and 104°F). Nausea and vomiting are common manifestations. Minor hemorrhagic manifestations such as epistaxis and bleeding gums may be observed. This period of infection may last for approximately 3 days, at which time the congestion declines and a relative bradycardia may occur despite the elevated temperature (Faget sign). The temperature falls to or below normal, and the patient feels better.

In most patients, this period of remission signals the beginning of convalescence; but in severe cases, it may last only a few hours, after which the patient enters a “period of intoxication” characterized by venous congestion and extreme bradycardia, despite a secondary rise in temperature.¹⁰ Nausea and vomiting are severe and associated with epigastric pain. Prostration and jaundice from liver failure, and marked albuminuria and anuria from renal failure are present. Hemorrhagic manifestations include hematemesis (“black vomit”) and melena.

The jaundice in some patients is not striking; it is difficult to detect in early disease and often is not detected until after death. The severity of hemorrhagic manifestations also varies greatly, but some hemorrhage can be found in most cases. As indicated earlier, minor hemorrhagic manifestations may be observed in the early stage of illness; severe hemorrhage usually develops late in the illness, although it may occur in fulminant cases as early as the second or third day. Hemorrhage may be so severe that it causes shock and death from blood loss. Albuminuria is one of the most common findings in yellow fever, and it occurs in all but very mild cases. It is present early in the illness and may increase rapidly. The albuminuria probably is related to renal involvement during the period of infection. Anuria, on the other hand, appears to be related to hepatic involvement and never is seen in the absence of other signs of liver infection. These terminal events may be related to “cytokine storm.” Involvement of the brain with viral encephalitis is rare in yellow fever, although the brain may exhibit edema and hemorrhages in fatal cases.

Death may ensue as early as 2 to 4 days after onset but occurs after 7 to 10 days of illness in 20% to 50% of severe cases. In patients in whom death occurs later, autopsy generally reveals a cause other than yellow fever. Patients with severe infection often have lowered resistance to secondary infection, which may develop at the time of convalescence. Other complications include kidney abscess, pneumonia, suppurative parotitis, and skin infection. Viral encephalitis is rare. Convalescence usually is rapid and complete except for a general weakness that may last for several weeks. Permanent damage to the liver or kidneys does not apparently occur in survivors.

PATHOLOGY

The gross pathologic findings in fatal cases of yellow fever are not striking.²⁵ The skin, sclerae, serosa, some internal organs, and subcutaneous fat usually have moderate icterus. Serous effusions, edema, and hemorrhages, including petechiae and purpuric lesions on the skin, conjunctivae, mucous membranes, stomach, duodenum, and bladder, often are present. Gastrointestinal hemorrhage may be prominent.¹⁵

The most characteristic lesions caused by yellow fever virus are seen in the liver, although liver failure is not generally the cause of death. The liver may have a yellowish color and be enlarged and fatty in consistency. In typical cases, marked necrosis of the midzone of the lobule is present. The necrosis extends both centrally and peripherally and on average involves 80% of the lobule in fatal cases.^{21,25} The cells bordering the central vein and portal areas usually are spared. Councilman and Torres bodies can be observed in hepatocytes and are characteristic of yellow fever. Little or no inflammatory response occurs, and the reticulin framework is preserved.

The kidneys generally are tense and swollen. Glomerular changes are minor, but acute tubular necrosis and fatty metamorphosis may be significant. Cloudy swelling, degeneration, and fatty infiltration may occur in the myocardial fibers. The spleen and lymph nodes are depleted of lymphocytes, and mononucleocytes or histiocytes accumulate in the follicles of the spleen. Edema and petechiae may be observed in the brain.

LABORATORY FINDINGS

Leukopenia and albuminuria are common findings in early stages of the disease.¹⁰ In severe cases, prolonged prothrombin and partial thromboplastin times, thrombocytopenia, fibrin split products, and elevated liver enzymes are observed. Total and conjugated serum bilirubin levels are elevated. Albumin levels in urine usually are less than 5 g/L, but in rare cases they may reach 40 g/L. The urine contains bile. Cerebrospinal fluid usually is normal but may be under increased pressure. Patients who are suspected of having or are diagnosed with yellow fever should have complete blood counts with platelet counts to detect leukopenia and thrombocytopenia; hemoconcentration with hemoglobin and hematocrit measurements, coagulation studies, and metabolic panel with electrolytes to detect elevated creatinine, metabolic acidosis, and hypoglycemia from liver failure; liver function tests to detect transaminitis and elevated direct bilirubin levels; and urinalysis to detect proteinuria and urobilinogen. Imaging studies include chest radiograph to detect cardiomegaly or pulmonary edema or pneumonia, electrocardiogram and cardiac monitoring for arrhythmias, and brain imaging to detect hemorrhages.

DIFFERENTIAL DIAGNOSIS

Yellow fever should be considered in patients living or traveling from endemic areas.¹⁰ Clinically, yellow fever is difficult to differentiate from many other viral, bacterial, and parasitic infections, including other viral hemorrhagic fevers such as Lassa, Ebola, Marburg, and Rift Valley in Africa; the illnesses caused by arenaviruses in the Americas; and dengue hemorrhagic fever in both continents. Other diseases that cause fever and jaundice, such as typhus, louse-borne relapsing fever, typhoid fever, viral hepatitis, hepatitis A, B, C, or E virus, leptospirosis, falciparum malaria, tick-borne relapsing fever, and Q fever, as well as other flavivirus infections with mild to moderate illness, such as Zika virus, West Nile virus, Chikungunya fever, and dengue virus, also should be considered in the differential diagnosis. Noninfectious causes of liver dysfunction including toxins and Reye syndrome should also be considered.

A definitive diagnosis of yellow fever can be made only by use of the appropriate laboratory test.

LABORATORY DIAGNOSIS

Specific laboratory diagnosis requires isolation of the virus or serologic, nucleic acid amplification, or immunohistochemical tests. Virus can be isolated most easily from acute-phase serum taken during the first 4 days of illness, but it has been isolated as long as 14 days after the onset of illness and from the liver after death.²⁵ The most sensitive method of virus isolation is inoculation of mosquitoes followed by AP-61 cell culture from *Aedes pseudoscutellaris* mosquitoes. Vero cells and inoculation of suckling mice also can be used but are less sensitive. Polymerase chain reaction (PCR) is highly sensitive, and yellow fever RNA can be amplified from these same tissues with a sensitivity higher than that of virus isolation.^{13,18} Viral antigen can be demonstrated in the liver by immunohistochemical methods.¹⁵ Either fresh or formalin-fixed tissue can be used with these techniques, which may be performed to establish a virologic diagnosis after virus has been cleared from the blood.

Serologic diagnosis depends on the collection of properly timed acute- and convalescent-phase serum samples to demonstrate a rise in specific antibody. Serologic tests commonly used to diagnose yellow fever include hemagglutination inhibition, complement fixation, and the plaque reduction neutralization test (PRNT), as well as newer tests, such as enzyme-linked immunosorbent assay (ELISA) for both immunoglobulin G (IgG) and IgM antibodies.¹⁴ The immunofluorescent assay is used in some laboratories.

Antibodies detected by hemagglutination inhibition, PRNT, immunofluorescent assay, and IgM capture ELISA appear within 5 to 7 days after the onset of illness.¹² The presence of a positive IgM test is diagnostic of recent yellow fever virus infection, as long as the patient has not had a recent yellow fever vaccine, which also may induce IgM antibodies. The complement fixation antibodies appear later than the other tests, usually after 10 to 14 days. Hemagglutination inhibition and PRNT antibodies persist at detectable levels for many years (>50) in most

patients, whereas the duration of complement fixation and IgM antibodies is uncertain, but they probably wane to undetectable levels after 12 to 18 months.

PRNT is the most sensitive and specific of the serologic tests.³² In patients who have had no previous flavivirus infection, this test can be used to make a specific diagnosis of yellow fever, as can IgM capture ELISA. Cross-reaction between yellow fever antigen and antibodies to other related flaviviruses complicates the serodiagnosis of this and other flavivirus diseases. Hemagglutination inhibition, immunofluorescent assay, and IgG ELISA are nonspecific tests in which considerable cross-reactivity with heterologous flavivirus antibodies occurs. Therefore positive results should be interpreted in clinical and epidemiological context.

The use of yellow fever 17D vaccine in disease-endemic areas also may complicate serologic diagnosis. Vaccination induces low-titer (1:10 to 1:40) hemagglutination inhibition and neutralizing antibodies but no detectable immunofluorescent or complement fixation antibodies. Vaccination also induces IgM antibody, which may remain at detectable levels for as long as 3 to 4 years.^{12,31} Vaccination of individuals who have had a previous flavivirus infection induces an anamnestic response of heterotypic flavivirus antibodies at high titer ($\geq 1:1280$).¹⁹

Yellow fever virus genome also may be detected by molecular methods such as quantitative real-time PCR and isothermal protocols that have been simplified and used in reference laboratories and point-of-care field situations.^{8,18,23}

TREATMENT

Treatment of yellow fever is primarily supportive. Patients with severe disease requiring hospitalization should have complete bed rest with good nursing care and close monitoring of vital organ functions. Salicylates should be avoided, but mild sedatives may be helpful. Maintenance of fluid and electrolyte balance is critical. Guidelines for intensive care of severe yellow fever cases have not been established. Secondary bacterial infections may occur and should be treated with appropriate antibiotics.

No specific antiviral therapy is licensed for treatment of yellow fever.^{10,21,23} However, ribavirin has activity against yellow fever virus and has been used to treat other *Flavivirus* infections.²⁶ In addition, investigations on the use of compounds such as T-705 and T-1106, as well as derivatives of the antibiotics doxorubicin and teicoplanin, as inhibitors of yellow fever virus replication are reported.^{7,16} Research and development for antiviral compounds effective against yellow fever virus continues, in novel areas such as lipid metabolism and carbohydrate-based inhibitors.^{17,20}

PROGNOSIS

Mortality in all yellow fever infections is low (<5%), but in severe cases requiring hospitalization, it may be 20% to 50%.^{21,25} The prognosis is poor for patients who enter a period of deterioration of clinical status with rapidly increasing albuminuria, jaundice, fever, and severe hemorrhage. Patients in the terminal stage of illness usually are somnolent, have below-normal temperatures, and may have intractable hiccups.

PREVENTION AND CONTROL

The most practical and cost-effective method of preventing yellow fever is vaccination.^{6,10}

A single dose of 17D-based live, attenuated yellow fever vaccine provides effective, long-term (10 years to life) protection and used in the World Health Organization (WHO) Expanded Program of Immunization in enzootic countries of Africa and the Americas.^{3,41} Two substrains of 17D strain of yellow fever virus (17D-204 and 17DD) are included in a live, attenuated vaccine dose of 10^5 plaque-forming units, which is manufactured in four countries in the world.¹¹ Yellow fever is the only disease where an international certificate of vaccination is required under International Health Regulations for travelers to endemic areas. In addition, yellow fever vaccination is recommended by the WHO to be included in routine infant immunization programs for infants older than 9 months in countries with endemic yellow fever. The vaccine is given every 10 years, although recently, the WHO stated that only one

yellow fever vaccination per lifetime is probably all that is necessary.²⁹ It is one of the most effective vaccines ever created, promoting well-characterized humoral neutralizing antibody and robust T-cell CD4⁺ and CD8⁺ cellular immunity responses.^{38,39} Also, CD4⁺ cells may be particularly important in preventing severe disease after wild-type yellow fever virus challenge in vaccinated animal models.³⁹ Detection of yellow fever IgG antibody persists for at least 10 years and possibly for life in some populations, and detection of yellow fever IgM antibodies may persist up to 3 to 4 years after vaccination, confounding serologic diagnosis of yellow fever in vaccinated travelers.¹²

The live, attenuated 17D vaccine was introduced in the 1930s and remains the mainstay of control of yellow fever in endemic zones of Central and South America and sub-Saharan Africa. The vaccine is prepared from infected chicken embryos and produces effective immunity in more than 95% of recipients.^{4,25} The same seed-lot system of vaccine production developed in 1945 is still used and contributes to limited vaccine availability. The vaccine is administered routinely to infants in endemic areas and also is used to provide protection for travelers to and residents of endemic areas of tropical South America, South Africa, and Africa. Traditionally, the vaccine is given every 10 years. However, in 2016, the WHO modified its guidance from a 10-year booster dosing schedule to a recommendation that one dose gives lifelong protection in most populations.⁵

The decision to administer yellow fever vaccine should include the geographic destination, season of the year, local evidence for yellow fever transmission, likelihood of exposure to vector mosquitoes, and individual risk factors for adverse events.^{4,27,28} Up to 25% of vaccines will have mild side effects, including injection site pain or redness, headache, malaise, and myalgia. Moderate to severe adverse reactions rarely occur and are categorized as neurotropic (“postvaccinal encephalitis”) or viscerotropic. Neurotropic complications occur at a rate of 1 per 5 million doses and with a case-fatality rate of 5%.^{10,11} Viscerotropic reactions are systemic illnesses that occur at a frequency of 4 million doses with a case-fatality rate of more than 50%. Severe adverse events occur more often in elderly persons, infants, and pregnant women.^{4,19,25,27} Elderly people appear to have a delayed antibody response and a prolonged viremia after vaccination, possibly leading to the higher incidence of adverse events in this group.^{19,31} Infants younger than 4 months have a high risk for development of encephalitis and should not be vaccinated with the live, attenuated 17D vaccine until they are 9 months of age. Pregnant women also should avoid being vaccinated because vaccine virus may infect the developing fetus, although the risk for adverse events associated with congenital infection is unknown. The live, attenuated 17D vaccine should not be given to persons who are allergic to eggs or to those who are immunodeficient or receiving immunosuppressive drugs.

In 2016, a yellow fever vaccine shortage occurred in Angola and the Democratic Republic of Congo.^{3,42} In response to this shortage, temporary fractional dosing of the vaccine was approved to meet the vaccine demands.⁴² In 2017, because of a manufacturing problem, a yellow fever vaccine shortage occurred in the United States, affecting immunization of US travelers.¹¹ The importation of an alternative yellow fever vaccine manufactured in France with safety and efficacy characteristics similar to the US licensed yellow fever vaccine may help address the US shortage.

The other method of preventing yellow fever is mosquito control, especially during epidemic activity. The principal mosquito vector of urban yellow fever, *A. aegypti*, is a highly domesticated species that lives in and around the houses of humans.^{2,13} It breeds primarily in artificial containers that collect rainwater or in domestic water storage containers and is notoriously difficult to control. The most sustainable and effective prevention, therefore, is to control, discard, or chemically treat larval

habitats in the domestic environment.^{2,13} This process is labor intensive but can be done with the help of the citizens in the community.

Some authorities recommend adult mosquito control with insecticide space sprays, primarily ultra-low-volume sprays. Recent field trials, however, have shown this approach to be ineffective unless portable sprayers are used to treat the inside of each dwelling. Because of the excessive cost and lack of efficacy of ultra-low-volume application of insecticides, this method is not recommended. Recently, the ability of the intracellular bacterium *Wolbachia* to reduce the replication of yellow fever virus in the mosquito vector *A. aegypti* shows promise for a novel biocontrol strategy for yellow fever.³⁴

Using mosquito repellants, wearing protective clothing (long sleeves, long pants, and mosquito netting), and using screened windows and doors in habitats and sleeping areas also will decrease exposure to mosquitoes bearing yellow fever virus.

Patients in whom yellow fever is suspected or proved should also be protected from mosquitoes to reduce spread of the virus. The most effective protection is to use a mosquito net on the bed during the acute febrile period of illness. Alternatively, patients can be kept in screened rooms. Effective repellents are available to treat clothing and exposed skin.

176D ■ Dengue, Dengue Hemorrhagic Fever, and Severe Dengue

Scott B. Halstead

Dengue fever is an acute febrile illness syndrome caused by several arthropod-borne viruses and characterized by biphasic fever, myalgia or arthralgia, rash, leukopenia, and lymphadenopathy. Synonyms are *dengue* and *breakbone fever*. Dengue hemorrhagic fever (DHF), a febrile disease syndrome caused by dengue viruses, is characterized

by abnormalities in hemostasis and leakage of fluid and protein from capillaries, which in severe cases result in shock (dengue shock syndrome [DSS]) (Box 176D.1). Both are manifestations of the dengue vascular permeability syndrome, an immune-complex mediated immunopathology.¹⁰⁷ Synonyms are *hemorrhagic dengue*, *acute infectious*

BOX 176D.1 World Health Organization 1997 Case Definition^a for Dengue Hemorrhagic Fever and Dengue Shock Syndrome

Dengue Hemorrhagic Fever

- Fever, or history of acute fever, lasting 2 to 7 days, occasionally biphasic
- Hemorrhagic tendencies, evidenced by at least one of the following:
 - A positive tourniquet test
 - Petechiae, ecchymosis, or purpura
 - Bleeding from the mucosa, gastrointestinal tract, injection sites, or other locations
 - Hematemesis or melena
 - Thrombocytopenia (100,000 cells per mm³ or less)
- Evidence of plasma leakage due to increased vascular permeability, manifested by at least one of the following:
 - A rise in the hematocrit equal to or greater than 20% above average for age, sex, and population
 - A drop in the hematocrit following volume replacement treatment equal to or greater than 20% of baseline
 - Signs of plasma leakage such as pleural effusion, ascites, and hypoproteinemia

Dengue Shock Syndrome

All of the above criteria for dengue hemorrhagic fever must be present, along with evidence of circulatory failure, manifested by the following:

- Rapid and weak pulse
- Cold, clammy skin and restlessness
- Narrow pulse pressure (<20 mm Hg)
- Hypotension for age

^aNo. 10693.

thrombocytopenic purpura, and *Philippine, Thai, Singapore hemorrhagic fever*. The 2009 World Health Organization (WHO) case definitions of *dengue*, *dengue with warning signs*, and *severe dengue* are provided in Box 176D.2. Useful general reviews are available.^{85,102,231}

The dengue subgroup is composed of four antigenically distinct members. In the first decade of the 21st century, based on records of dengue occurrences and modeling frameworks, dengue viruses were epidemic or endemic in 128 tropical countries, placing nearly 4 billion people at risk for infection and resulting in an estimated 390 million dengue infections. Of these infected people, 96 million developed clinical symptoms, 26.6 million sought medical care, and 2.5 million were hospitalized, with case-fatality rates in some countries of 5%.^{28,36,225,226,242} In tropical Asian countries, dengue is among the 10 leading causes of death in children 1 to 15 years of age.¹⁰⁰ Small indigenous outbreaks of dengue 1 occurred in Hawaii in 2001 and 2015–16 and in Key West, Florida, in 2009 to 2011^{68,195} (<http://health.hawaii.gov/docd/dengue-outbreak-2015/>). Dengue infections are major causes of febrile illnesses in tourists to tropical destinations, some of whom develop life-threatening disease.^{267–269}

The term *dengue*, of Spanish origin, came into use in 1828 during a Cuban outbreak that undoubtedly was *chikungunya*.^{44,108} The Swahili term for *chikungunya*, *ki denga pepo*, had been used to describe an 1823 outbreak on Zanzibar.⁵² The first outbreak that resembled a disease now recognized clinically and epidemiologically as dengue fever was described by Benjamin Rush in Philadelphia in 1780.²¹⁴ Epidemics probably caused by dengue viruses were common from the 18th century onward in inhabitants of the Atlantic coastal areas of the United States and South America, the Caribbean islands, and the Mississippi basin.²²⁹ Dengue viruses almost certainly were the cause of the 5- and 7-day fevers that occurred in European colonists in tropical Asia. Similar epidemics occurred commonly in settlers in tropical Australia, where in 1905 *Aedes aegypti* was identified as a dengue vector by Bancroft.²¹ Ashburn and Craig first found the etiologic agent in human blood and showed that it could pass through a diatomaceous earth filter.¹⁶ An intrinsic incubation period of 3 to 8 days in humans, an extrinsic

BOX 176D.2 World Health Organization 2009 Case Definition^a for Dengue

Probable Dengue

The patient lives in or travels to dengue-endemic area and has a fever and two of the following:

- Nausea, vomiting
- Rash
- Aches and pains
- Positive tourniquet test
- Leukopenia
- Any “warning sign”

Dengue With Warning Signs

- Abdominal pain or tenderness
- Persistent vomiting
- Clinical fluid accumulation
- Mucosal bleed
- Lethargy, restlessness
- Liver enlargement >2 cm
- Laboratory increase in HCT concurrent with rapid decrease in platelet count

Severe Dengue (Short Form)

- Severe plasma leakage
- Shock (DSS)
- Fluid accumulation with respiratory distress
- Severe bleeding (as evaluated by clinician)
- Severe organ involvement
- Liver AST or ALT ≥1000
- CNS-impaired consciousness
- Heart and other organs

Severe Dengue (Long Form)

- Evidence of plasma leakage, such as the following
 - High or progressively rising HCT
 - Pleural effusions or ascites
 - Circulatory compromise or shock (tachycardia, cold and clammy extremities, capillary refill time >3 seconds, weak or undetectable pulse, narrow pulse pressure, or, in late shock, unrecordable blood pressure)
- Significant bleeding
- An altered level of consciousness (lethargy or restlessness, coma, convulsions)
- Severe gastrointestinal involvement (persistent vomiting, increasing or intense abdominal pain, jaundice)
- Severe organ impairment (acute liver failure, acute renal failure, encephalopathy or encephalitis, cardiomyopathy) or other unusual manifestations

^aNo. 13630.

ALT, Alanine aminotransferase; AST, aspartate aminotransferase; CNS, central nervous system; DSS, dengue shock syndrome; HCT, hematocrit.

incubation period of 8 to 11 days in mosquitoes, immunity in humans and monkeys, and the nonsusceptibility of most domestic animals were demonstrated in the classic studies of Siler and associates²²⁹ and Simmons and coworkers²³² in the Philippines between 1924 and 1930. When dengue viruses were isolated in laboratory mice in 1943 and 1944, the modern era of dengue research began.^{147,217} Two strains from Hawaii and Papua New Guinea failed to cross-protect humans. From this experiment, researchers recognized the existence of at least two different dengue viruses; they were named *dengue viruses type 1 and type 2*.^{216,217,235}

During most of the previrologic era, dengue viruses were thought to be the cause of a generally benign, self-limited febrile exanthem. However, death, shock, and severe hemorrhagic manifestations

accompanied classic dengue fever outbreaks in Australia in 1897 and thereafter for 15 years. Similar phenomena were recorded in Greece in 1928 and in Formosa in 1931.⁹¹ This “new” syndrome was recognized again in Manila in 1954. It was called *Philippine hemorrhagic fever* because of a resemblance to the epidemic hemorrhagic fever then occurring in United Nations troops on the Korean Peninsula.¹⁹⁴ In 1956, Philippine hemorrhagic fever was associated with dengue when types 3 and 4 were recovered.¹¹⁸ All four dengue viruses are now endemic in tropical countries throughout the globe.²⁸ In 1966, the terms *dengue hemorrhagic fever* and *dengue shock syndrome* came into general use.¹¹⁰ In 2009, a WHO committee advised that these terms be subsumed under the diagnostic categories of “dengue with warning signs” and “severe dengue.”²⁷⁷

By epidemiologic criteria, dengue viruses are arthropod-borne (arboviruses) because they are transmitted biologically by various members of the genus *Stegomyia*.¹⁶⁷ Gene structure, replicative strategy, and antigenic relatedness place the dengue viruses in the family *Flaviviridae*.^{143,262} At present, 68 members of the flavivirus family have been identified; 29 of them are established as human pathogens.¹⁴³ Cross-comparisons by plaque-reduction neutralization tests have shown dengue viruses to be an antigenic subgroup.⁶⁰ In addition to their antigenic relatedness and their ability to be transmitted by *Stegomyia*, each type of dengue virus produces a closely similar clinical syndrome in susceptible humans.^{93,140,182,216,229,232}

Dengue is an enveloped, positive-strand RNA virus that produces a spherical particle with a diameter of approximately 500Å. Dengue RNA consists of approximately 11,000 nucleotides coding from the 5' end for core, premembrane, envelope, and five nonstructural proteins.^{48,90} The crystal structures of the E protein of several dengue viruses have been solved.^{171,170,172} The viral envelope contains two membrane proteins, envelope (E) and premembrane (prM). Individual subunits of E protein consist of three β -barrel domains designated domains I (EDI), II (EDII), and III (EDIII). These proteins form head-to-tail homodimers. Each virus particle has 180 monomers of E that are organized into 90 tightly packed dimers that lie flat on the surface of the viral membrane. Individual E subunits are organized in twofold, threefold, and fivefold axes of the T-3 icosahedral structure of the virion. E protein subunits are not placed in identical environments on the viral surface. The hydrophobic viral fusion peptide is located at the tip of domain II and is shielded by domain III of the adjacent subunit. Steric and other considerations can result in preferential interactions of some E subunits over others with receptors and antibodies. The E proteins, the main target of neutralizing antibodies, bind to cellular receptors and mediate fusion of viral and cellular membranes during viral entry into cells. Domain III appears to be responsible for binding to cellular receptors. The structural arrangement of viral surface proteins plays an important role in dictating how antibodies neutralize viruses.

When the virion is assembled the envelope protein bears quaternary epitopes unique to serotypes. These quaternary epitope pockets are bounded variously by domains II, III, and I.^{58,71,76,260} Antibodies directed to these epitopes neutralize by hindering viral attachment to cell receptors or fusion entry into cells.^{192,260} Other structural epitopes are shared between dengue viruses (dengue subgroup antigens) and other flaviviruses (group antigens).

Four clearly defined types exist, as determined by plaque-reduction neutralization tests using antibodies raised by infection of monkeys or fluorescent antibody tests using monoclonal antibodies raised in mice.²¹⁵ The four types have distinctive genetic structures and antigenic structures separable by homotypic antibodies.^{60,120,144,266} Phylogenetic studies suggest that human dengue viruses diverged from four zoonotic dengue types relatively recently, whereas the four zoonotic types evolved in subhuman primates from a common viral ancestor in the more remote past, most likely in Indonesia.^{122,257,262} Sylvatic dengue viruses retain the capacity to infect and cause disease in humans.^{42,254,255} Different dengue strains cluster in groups that differ genetically (genotypes).^{53,54,200,201,249} Genotypes consist of viruses of similar genetic structure that usually circulate within one geographic area.²⁴⁹ Genotyping can be used to trace the movement of dengue viruses between persons over short and long distances.¹³⁷ Of particular interest, a strain of dengue type 2 isolated in Jamaica in 1981 and the dengue 2 viruses recovered from 1981 Cuban DHF patients belong to a Southeast Asian genotype.^{200,218} The most sharply divergent

genetic differences are among human viruses and strains from Asian and African zoonotic cycles.^{200,257,262}

Dengue virus can be grown in 1- to 2-day-old mice or hamsters by intracerebral inoculation or in various mosquitoes by oral or parenteral inoculation. High mouse-passaged virus grows and produces deaths in weanling mice. Various tissue cultures of vertebrate and invertebrate origin support dengue virus growth in vitro, as reviewed in the following section.

TRANSMISSION

A. aegypti, a crepuscular daytime-biting mosquito, is the principal vector. All four virus types have been recovered from naturally infected *A. aegypti*.⁹¹ In most tropical areas, *A. aegypti* is highly domesticated and breeds in water stored for drinking, washing, or bathing or in any container collecting fresh water. Dengue viruses also have been recovered from naturally infected *Aedes albopictus*, which breeds outdoors in vegetation.^{68,91} Outbreaks in the Pacific area have been attributed to *Aedes scutellaris* and *Aedes polynesiensis*.²¹⁰

Transmission of dengue by *A. aegypti* may be explosive and involve as much as 70% to 80% of the population.²²⁹ Because *A. aegypti* has a limited flight range, spread of virus is mainly by mobile viremic humans.^{197,234,280} Transmission of dengue viruses by *A. albopictus* results in indolent, long-duration small outbreaks, as exemplified by the introduction of dengue virus type 1 into Hawaii in 2001.⁶⁸

Dengue viruses replicate in the gut, brain, and salivary glands of infected mosquitoes without apparent harm to adult mosquitoes.²⁰⁷ Mosquitoes are infectious for a lifetime and for as long as 70 days in experimental circumstances.²³² Because female mosquitoes take repeated blood meals, long-lived female mosquitoes have great potency as vectors.¹¹³ Several species of *Stegomyia* are infected readily by intrathoracic inoculation, although the threshold for infection by oral feeding is higher.^{207,206} *A. aegypti* and *Culex quinquefasciatus* can transmit dengue mechanically by interrupted feeding.²³² The contribution of mechanical feeding to the spread of dengue virus during epidemics has never been measured. Because of the “skittishness” of *A. aegypti* and its habit of feeding during the day when its intended victim is awake and often moving, interrupted feeding with simultaneous transmission to multiple hosts within a household must be a common occurrence.

A. aegypti preferentially feeds on people and hence is most abundant in and around human habitations. The mosquito breeds in clean water. Biting activity is reduced at temperatures below a wet bulb temperature of 14°C (57.2°F).^{37,38,63} Transmission of dengue in temperate countries is interrupted during winter weather, and dengue has not established itself endemically at latitudes above 25 degrees north or south. Breeding sites may be provided by humans through living habits, as in Thailand, where water is stored in and around homes in large earthenware jars.^{91,98} In contrast, *A. aegypti* is not abundant in some parts of India because only small amounts of water are brought to homes from village wells for immediate use. Water in flower vases, household offerings, ant traps, coconut husks, tin cans, and rubber tires may supply breeding sites for *A. aegypti*.⁸¹

In the tropics, outbreaks of dengue generally coincide with the monsoon season. Eggs, which resist desiccation, are deposited inside water containers above the water line.⁸¹ With the beginning of monsoon rains, a large number of eggs laid outdoors are hatched.^{103,223} Indoor populations do not show seasonal change. Temperature is important in controlling viral transmission. Evidence indicates that the extrinsic incubation period shortens with increasing mean temperatures; mosquito biting rates increase with increased temperature and relative humidity.²²⁷

In sylvan settings, dengue virus has been isolated from three subgenera of *Aedes*, namely, *Stegomyia*, *Diceromyia*, and *Finlaya*, some in circumstances suggesting the occurrence of transovarial transmission. This phenomenon has been demonstrated experimentally, but its contribution to maintenance of virus in a habitat is unknown.²¹¹

EPIDEMIOLOGY

Host Range

Inoculation of strains of dengue with known human pathogenicity does not produce demonstrable infection in adult chickens, lizards,

guinea pigs, rabbits, hamsters, or cotton rats.^{221,232} Subhuman primates generally are susceptible to infection by dengue viruses. Numerous species belonging to *Macaca*, *Cercopithecus*, *Cercocebus*, *Papio*, *Hylobates*, and *Pan* can be infected by the bite of virus-infected mosquitoes or by injection of infectious virus preparations.^{109,219,220,232} Infection is essentially asymptomatic. Viremia occurs at levels sufficient to infect mosquitoes. Simmons and colleagues were the first to note that wild-caught *Macaca philippinensis* resisted dengue infection, whereas *Macaca fuscatus* (Japanese macaque) was susceptible.²³² Work by Rudnick in Malaysia has revealed a jungle cycle of dengue transmission involving canopy-feeding monkeys and *Aedes niveus*, a species that feeds on both monkeys and humans.²¹³ Although the existence of a jungle dengue cycle in the Malaysian rain forest has been documented, the full geographic range of the subhuman primate zoonotic reservoir in Asia is not known.²⁵⁵ In the 1980s and 1990s, extensive epizootics of dengue virus type 2 involved subhuman primates over wide areas of West Africa.^{204,256} Genetic and epidemiologic studies have shown that urban human dengue and jungle monkey dengue are only relatively compartmentalized.^{200,254,255,262} Urban dengue is vectored by anthropophilic mosquitoes, and the virus travels with people along routes of transportation.^{159,234} *A. aegypti* and susceptible humans are so abundant and so widespread that should dengue viruses be exchanged between humans and monkeys, detection would be extremely difficult. If, in the future, urban dengue is eliminated but vector mosquito populations are unabated, dengue viruses may once again be introduced from jungle cycles.

Geographic Distribution

Outbreaks of dengue fever have been documented on every continent except Antarctica.^{28,36,38} Evidence suggests that human dengue may have originated from enzootic subhuman primate foci in tropical Asia.^{255,262,264} *A. aegypti* originated in Africa where its ancestral form was a tree hole–breeding mosquito named *A. aegypti formosus*.³⁹ This mosquito evolved into a domestic form in Africa.⁴⁰ The spread of *A. aegypti* during historical times from Africa throughout the world provided an ecologic niche quickly occupied by several human viral pathogens: yellow fever, chikungunya, Zika, and the dengue viruses.³⁹ During the 18th and 19th centuries, epidemics occurred in newly settled lands, largely because of the necessity for storage of domestic water in frontier areas. Isolated shipboard or garrison outbreaks often confined to nonindigenous settlers or visitors were reported in Africa, the Indian subcontinent, and Southeast Asia.^{44,43,162,229} During World War II, dengue virus infections occurred commonly in combatants of the Pacific War and spread to staging areas not normally infected—Japan, Hawaii, and Polynesia.^{104,100,216} DHF-like disease was described clinically in Thailand beginning in 1950 and in the Philippines from 1953; cases were confirmed etiologically as dengue in 1958 and 1956, respectively.^{110,117,118} DHF was described in Singapore and Malaysia in 1962, Vietnam in 1963, India in 1963, Ceylon (Sri Lanka) in 1965, Indonesia in 1969, Burma (Myanmar) in 1970, China in 1985, and Kampuchea and Laos from about 1985; major outbreaks have occurred in Sri Lanka and India since 1988, in French Polynesia since 1990, in Pakistan since 1998, and in Bangladesh since 1999.^{96,104,100} DHF has occurred at consistently high endemicity in Thailand, Burma, Vietnam, Cambodia, Laos, Philippines, India, and Indonesia.¹⁰⁴ Since 2008, repeated outbreaks have occurred in Pakistan.¹²⁹ In Thailand, DHF is the third ranking cause of hospitalization and death in children. Intermittent epidemics have involved the Maldives, Singapore, and Bangladesh.

During the past 20 years, major epidemics of all four dengue serotypes have occurred on several Pacific islands, with repeated severe epidemics on Tahiti, and in 2001, with a subsequent introduction into Hawaii.^{54,68,83,100,127}

American genotype dengue 2 virus circulated in the American hemisphere for hundreds of years and was the only virus to survive an intensive period of control of *A. aegypti* designed to eradicate urban yellow fever.^{6,81} In 1963, an Asian strain dengue 3 was introduced into the Caribbean and died out in the 1980s. Dengue viruses became fully established in the hemisphere after the introduction of a Southeast Asian dengue 1 in 1977.^{62,101} Dengue 1 spread rapidly and now is endemic on the larger Caribbean islands and in Mexico, coastal Central America, and the tropical areas of Guyana, Venezuela, Colombia, Ecuador, Peru,

Bolivia, and Brazil.¹⁰¹ A sharp dengue virus type 2 epidemic in Cuba in 1981 involving 116,000 hospitalizations in a 3-month period led to apparent eradication of *A. aegypti*, but reintroduction of dengue type 2 into Santiago de Cuba in 1997 and type 3 in Havana in 2001 resulted in particularly severe outbreaks of DHF.^{3,88,153} In 1981, an Asian dengue 4 was introduced into the Caribbean, spread widely, and now is endemic throughout the Caribbean basin. In 1986 and 1987, dengue virus type 1 spread through most of coastal Brazil and from there to Paraguay, Peru, and Ecuador.¹⁹⁶ In 1990, more than 9000 dengue cases were reported from Venezuela; 2600 of them were classified as DHF, and 74 deaths were associated with the epidemic.¹⁹⁶ Dengue virus types 1, 2, and 4 were isolated.¹⁹⁶ Shortly thereafter, DHF/DSS caused by dengue type 2 was reported from Brazil and French Guiana.^{184,198} In 1994, dengue virus 3 was introduced into the region, and dengue 4 in 2010.^{70,101} All four dengue virus types are now endemic in most of Brazil. Initially, in the Americas, because the population was dengue naïve owing to decades of mosquito control, most dengue infections produced disease in adults, and occasionally severe disease in older individuals with preexisting chronic diseases but with low mortality. As two or more dengue viruses became endemically established, classic DHF was recognized throughout most of South and Central America, with severe disease increasingly involving children.^{101,205}

In the 1960s, dengue viruses 1 and 2 were recovered from humans with mild clinical illnesses in Nigeria in the absence of epidemic disease.⁴⁵ In 1983, dengue virus type 3 was isolated in Mozambique.⁴ Since then, all four dengue virus types have been recovered from individuals with febrile diseases in much of Africa or in nonindigenous persons living in or returning from Africa.⁴ Dengue virus type 3 infections were notable in the past decade with a sharp outbreak of classic dengue fever observed in adults on the Cape Verde islands, and cases and deaths resulting from classic DHF/DSS in Kassala, Sudan, and Port Sudan on the Gulf of Aden.^{61,1,163} In sub-Saharan Africa, DHF/DSS have not been reported and even dengue fever outbreaks are rare, although a substantial outbreak was reported in Angola in 2013.^{187,222} In this respect, sub-Saharan Africa resembles the situation in Haiti, where multiple dengue serotypes are transmitted at high rates among a predominantly black population but severe disease is not recognized.^{115,136,202}

CLINICAL MANIFESTATIONS

Dengue Fever

In children, clinical manifestations of both primary and secondary dengue infections are varied and often mild. Duration and degree of fever are highly variable. When brought to the attention of health care workers, the disease often presents with upper respiratory tract symptoms and signs and/or gastrointestinal disturbances. Patients often have leukopenia, positive tourniquet test, cough, and pharyngeal injection. Maculopapular rash, petechiae, facial flush, liver enlargement, and cool extremities are observed infrequently but at similar frequency in children with primary or secondary dengue infections.^{77,112,142,174}

When studied in the open population, primary infections with dengue virus types 2 and 4 are largely inapparent.^{73,88,258} By contrast, primary infections with dengue virus types 1 and 3 in children somewhat more often result in mild to moderate febrile disease, sometimes accompanied by low-grade vascular permeability. Epistaxis, petechiae, and purpuric lesions are uncommon manifestations but may occur at any stage of the disease. Swallowed blood from epistaxis may be passed per rectum or be vomited and could be interpreted as bleeding of gastrointestinal origin.

Because chikungunya and the dengue viruses are transmitted by the same vector mosquitoes, the diseases frequently are observed in the same patient populations. Chikungunya virus, now distributed globally in the tropics, produces a dengue fever–like syndrome. Chikungunya illnesses begin more abruptly than dengue illnesses and are of shorter duration. Maculopapular rash, conjunctival injection, and myalgia or arthralgia occur more frequently in chikungunya than in dengue illnesses, but other features associated with both viruses are remarkably similar.^{44,112,182} Similarities and differences in mild dengue syndromes, hospitalized dengue cases (predominantly during secondary dengue virus infections), and chikungunya illnesses are illustrated in the Chapter 175D.

In classic dengue fever (seen most frequently in adults), after an incubation period of 2 to 7 days, patients experience a sudden onset of fever, which rapidly rises to 39.5°C to 41.4°C (103°F–106°F) and usually is accompanied by frontal or retroorbital headache. On occasion, back pain precedes the fever. A transient, macular, generalized rash that blanches under pressure may be seen during the first 24 to 48 hours of fever. The pulse rate may be slow in proportion to the degree of fever. Myalgia or bone pain occurs soon after onset and increases in severity. During the second to sixth day of fever, nausea and vomiting are likely to occur, and generalized lymphadenopathy, cutaneous hyperesthesia or hyperalgesia, aberrations in taste, and pronounced anorexia may develop. One or 2 days after defervescence, a generalized morbilliform, maculopapular rash appears, with sparing of the palms and soles. It disappears in 1 to 5 days. In some cases, edema of the palms and soles may be noted, and desquamation may occur. About the time of appearance of this second rash, the body temperature, which has fallen to normal, may become elevated slightly and establish the biphasic temperature curve.

A dengue 2 strain circulating in Cuba in 1997 produced predominantly silent primary infections in adults and children.⁸⁸ Primary infections with dengue 1 and 3 viruses in adults are often overt with biphasic fever, rash, myalgia, anorexia, and gastrointestinal disturbances as characteristic features.^{72,73,232} In Taiwan, primary dengue 1 infections in individuals with peptic ulcer resulted in gastrointestinal hemorrhage, in some cases severe.²⁵³ This syndrome may be confused with DSS (see later discussion) and contribute to a misunderstanding of its pathogenesis. Gastrointestinal bleeding, menorrhagia, and bleeding from other organs have been observed in many outbreaks of dengue fever.^{199,253,265} The mechanism of the hemorrhagic diathesis that commonly occurs with primary dengue virus infections is not known. In some cases, dengue infections, whether primary or secondary, in adults or elderly people, particularly those with diabetes, asthma, or hypertension, are serious and pose a risk for death.^{157,186,191,248}

Dengue Hemorrhagic Fever, Dengue Shock Syndrome, and Severe Dengue

The dengue vascular permeability syndrome (DVPS) is the core pathophysiologic phenomenon in DHF/DSS and severe dengue (Box 176D.3).^{12,107,241} The incubation period of DVPS is unknown but is presumed to be the same as that of dengue fever. In infants and children, progression of the illness is characteristic.^{56,155,182,250-252,272} A relatively mild first phase with an abrupt onset of fever, malaise, vomiting, headache, anorexia, and cough may be followed after 2 to 5 days by acute midepigastria abdominal pain, lassitude, then rapid deterioration and physical collapse. In Thailand, the median day of admission to the hospital after the onset of fever is day 4. In this second phase, the patient usually has cold and clammy extremities, a warm trunk, flushed face, diaphoresis, and anuria. Patients are lethargic or restless and irritable and complain of midepigastria pain. Frequently, scattered petechiae appear on the forehead and extremities, spontaneous ecchymoses may develop, and easy bruisability and bleeding at sites of venipuncture are

common findings. Circumoral and peripheral cyanosis may occur. There is slow venous filling time. Respirations are rapid and often labored. The pulse is weak, rapid, and thready, and the heart sounds are faint. Systolic pressure may remain normal or even elevated, and the patient appears deceptively well, retaining full consciousness. When hypotension ensues, the pulse pressure becomes narrow (<20 mm Hg) and systolic and diastolic pressures fall rapidly and may become unobtainable. The liver may become palpable two or three fingerbreadths below the costal margin and usually is firm and nontender. Chest radiographs may show unilateral (right) or bilateral pleural effusions. Ultrasonographic evidence of plasma leakage may be detected in some cases within 3 days after fever onset. Pleural effusion is the most common ultrasonographic sign of plasma leakage (62% of DHF cases 1 day after defervescence). Thickening of the gallbladder wall, postvesicular edema, and ascites are detected less frequently and resolve more rapidly than pleural effusions.^{238,239} Up to 10% of patients may have gross ecchymosis or gastrointestinal bleeding. During the transition from the febrile to the critical phase, it is crucial for the clinician to be aware of warning signs of impending vascular permeability: persistent vomiting, increasingly severe abdominal pain, rising hematocrit, and falling platelet count. After a 24- or 36-hour period of crisis, convalescence is fairly rapid in children who recover. The temperature may return to normal before or during the stage of shock.

It should be noted that DVPS occurs regularly in infants in countries where multiple dengue viruses are hyperendemic.^{111,130,131,179} These babies are born to mothers with two or more lifetime dengue infections but do not occur when mothers have experienced only a single dengue infection before pregnancy.^{46,50,149} Infants, predominantly aged 5 to 10 months, experience physiologically the same dengue vascular permeability syndrome as older children, except that they are more difficult to diagnose and treat and their case-fatality rates are higher.^{130,131,141,179}

Case Definitions

Dengue Fever, Dengue Hemorrhagic Fever, and Dengue Shock Syndrome

Case definitions were introduced in Thailand in the 1960s to assist pediatricians in outpatient settings to identify patients with acute dengue infections and to initiate triage.¹¹⁰ A positive tourniquet test, thrombocytopenia, and enlarged liver were regarded as a case of “dengue,” whereas an elevated hematocrit suggested vascular leakage (see Box 176D.1). These diagnostic criteria were applied successfully over 30 years in several Southeast Asian countries, successfully reducing mortality rates.^{9,52,181} In retrospect, this success could be attributed to the widespread availability of microhematocrit centrifuges in outpatient facilities and the stationing of centrifuges on hospital wards where they were widely used by staff. Frequent microhematocrit determinations made possible the rapid and responsive management regimen as described in WHO case management recommendations.⁹ Defining DHF/DSS proved difficult because estimates of 20% hemoconcentration could only be made in retrospect, comparing convalescent hematocrit values with those obtained during acute illness. Except during formal research studies, this requirement was seldom satisfied. Accordingly, DHF was a clinically based diagnosis without a “hard” diagnostic end point.

Dengue Fever Warning Signs and Severe Dengue

When multiple dengue viruses of Southeast Asian origin successfully invaded the American hemisphere beginning in 1977, DVPS gradually emerged throughout the region. Two major epidemiologic differences were noted between dengue in the Americas and in Asia: disease was common in susceptible adults and was predominantly the dengue fever syndrome.¹⁰¹ A few severe cases occurred in adults, but over time more severe cases including classic shock syndrome and deaths were observed. In the Americas, the predominant hospital management system specified that hematocrit centrifuges be located in pathology laboratories. Thus inexpensive and easy access to multiple microhematocrit determinations was not available. This obstacle generated a movement to bypass the quantitative, laboratory-based 1997 WHO case definitions in favor of the qualitative descriptors of the 2009 WHO Technical Guideline (see Box 176D.2). The rationale for developing and the experience with these case definitions have been extensively documented.^{22,123-126}

BOX 176D.3 Dengue Vascular Permeability Syndrome

A dengue syndrome that occurs late in the course (on or near defervescence) of an acute dengue illness consisting of:

- Thrombocytopenia
- Altered hemostasis: most commonly prolonged bleeding time and/or elevated activated partial thromboplastin time and/or elevated prothrombin time
- Activated complement, by classical and alternative pathways
- Elevated liver transaminase enzymes
- Vascular permeability: clinically significant loss of fluid and small macromolecules (e.g., albumin) into interstitial spaces, most commonly to serosal cavities

A useful focus of the 2009 WHO case definitions is the effort to alert clinicians through clinical signs to anticipate onset of dengue vascular permeability (dengue with warning signs). But the suggestion that all patients with a warning sign be hospitalized has resulted in vast overhospitalization as in, for example, the 2011 classical dengue fever epidemic in Pakistan. In addition, the diagnosis of severe dengue includes a broader range of pathologic responses to dengue infections than did the earlier DHF, which included cases classified as “unusual dengue.” These cases include altered levels of consciousness, severe liver disease, acute renal failure, cardiomyopathy, respiratory distress, and severe bleeding. Many of these are end-stage syndromes that may follow prolonged shock or are due to comorbidities. More problematic is identifying those patients who are in respiratory distress because of fluid overload as having severe dengue. This labels as severe dengue an all too frequent iatrogenic complication caused by administration of excess intravenous fluid. In this way inadequate patient management may be confused diagnostically and epidemiologically as an instance of the vascular permeability shock syndrome.

PATHOLOGY AND PATHOGENESIS

Using relatively insensitive virus recovery systems, tissue cultures and suckling mice, recovery of dengue virus is difficult and usually absent in tissues at the time of death.^{183,208} If patients experienced a second dengue infection, their tissue suspensions contain large quantities of dengue-neutralizing antibodies. The use of mosquito inoculation techniques improves viral isolation rates.^{207,206,209} Genetic probes increase viral detection sensitivity still further.^{18,128,208} In humans, dengue viruses infect and replicate efficiently in intracutaneous Langerhans cells in vitro and in tissue explants.²⁷⁸ Virus ultimately targets liver parenchymal cells, where infection produces apoptosis, but hepatocytes may not serve as replicative hosts.^{18,57,128,165} Late in infection, virus is found associated in circulating monocytes.⁶⁶ Fluorescent antibody, virus isolation, electron microscopic, and in situ hybridization studies suggest that tissue mononuclear phagocytes are major hosts for dengue infection.^{18,19,27,29,34,35,279}

On pathologic examination, usually no gross or microscopic lesions are found that might account for death.²⁷ In rare instances, death may be caused by gastrointestinal or intracranial hemorrhage. Minimal to moderate hemorrhage is seen in the upper gastrointestinal tract, and petechial hemorrhage occurs frequently in the intraventricular septum of the heart, on the pericardium, and on the subserosal surfaces of major viscera. Focal hemorrhaging is seen occasionally in the lungs, liver, adrenals, and subarachnoid space. The liver usually is enlarged, often with fatty changes. Yellow, watery, at times blood-tinged effusions are present in serous cavities in approximately three-fourths of patients. Retroperitoneal tissues are markedly edematous. On microscopic examination, perivascular edema in soft tissues and widespread diapedesis of red blood cells can be seen. Maturation arrest of megakaryocytes may be noted in the bone marrow,^{30,175,177} and increased numbers of such megakaryocytes are seen in the capillaries of the lungs, in the renal glomeruli, and in the sinusoids of the liver and spleen. Proliferation of lymphocytoid and plasmacytoid cells, lymphocytolysis, and lymphophagocytosis occur in the spleen and lymph nodes.²⁷ In the spleen, evidence shows infected tissue macrophages, and malpighian corpuscle germinal centers are necrotic.^{18,176} Depletion of lymphocytes occurs in the thymus. In the liver, widespread evidence of infection with varying degrees of fatty metamorphosis, focal midzonal necrosis, and hyperplasia of Kupffer cells is present.^{18,19,27,138,176} Dengue infection of hepatocytes may result in apoptosis, with evidence of assembled virions lacking.^{18,57,138,166} Nonnucleated cells with vacuolated acidophilic cytoplasm resembling Councilman bodies (apoptotic hepatocytes) are seen in the sinusoids.^{18,26,128} A mild, proliferative glomerulonephritis is present. Biopsy specimens of the rash reveal swelling and minimal necrosis of endothelial cells, subcutaneous deposits of fibrinogen, and, in a few cases, dengue antigen in extravascular mononuclear cells and on blood vessel walls.³⁵

Epidemiologic, clinical, and virologic studies of DHF/DSS in humans have shown a significant association between the dengue vascular permeability syndrome and dengue virus infection in the presence of

circulating dengue antibody, whether it is passively acquired from the mother or actively acquired from previous infection. Risk for developing vascular permeability syndrome is inversely correlated with age; the youngest children are at highest intrinsic risk.^{5,87} In humans, circulating antibody appears to have two biologic activities: neutralization of virus and enhancement of infection.^{99,97} In Thailand and Vietnam, DHF/DSS developed in infants during dengue virus type 2 infection only when maternal neutralizing antibody had catabolized to low titer and infection-enhancing antibodies were left in circulation.^{49,111,149,178,230} Similarly, in a prospective study of dengue virus infection in Thai children, DHF/DSS occurred in children who had circulating enhancing antibodies from a previous single dengue virus infection, but it did not occur in children whose first infection left them with low levels of cross-reactive dengue virus type 2 neutralizing antibody at the time of the second dengue virus infection.¹⁵⁰ It is now known that heterotypic protective immunity spaces clinically second severe dengue infections to at least 2 or more years after first infections.⁷ Cross-protective immunity may also explain the failure of secondary infections to produce DHF/DSS with the American genotype dengue type 2.²⁶³ American genotype dengue 2 viruses are significantly neutralized by human anti-dengue 1, whereas Southeast Asian dengue 2 viruses are not.^{151,152}

In rhesus monkeys experimentally infected with dengue virus by subcutaneous inoculation, virus replicates initially in the skin. Virus disseminates rapidly to regional lymph nodes and then to lymphatic tissue throughout the body.¹⁶⁴ Early in the viremic period, virus can be recovered only from the skin inoculation site and lymph nodes, whereas 2 to 3 days later, evidence of general dissemination to skin and other tissues is found. Virus is recovered from the skin, lymph nodes, and several leukocyte-rich tissues for up to 3 days after termination of viremia. Virus can be recovered from circulating leukocytes and from the skin only at the end of the viremic period. The number of sites from which virus can be recovered increases as the infection progresses. Intracellular infection is terminated abruptly 2 to 3 days after viremia ceases.

Monkeys infected initially with dengue viruses 1, 3, or 4 and then with dengue virus 2 had higher viremia than when the same virus was inoculated into susceptible animals.^{95,114} A similar phenomenon was observed in monkeys given diluted human polyclonal dengue antibodies and then challenged with dengue 2 virus.⁹⁴ This phenomenon, in vivo antibody-dependent enhancement of dengue infection, provides an explanatory hypothesis of the immunopathogenesis of dengue in humans.^{99,105,106}

Dengue pathogenesis models have been developed in mice that lack interferon receptors. Dengue virus dose-dependent early infection events result in severe vascular permeability.^{19,228} Of importance, dengue antibody concentrations modulate infection in Fc receptor-bearing cells across a range of responses from protection to enhancement.^{20,228,282,283} To date, mutant dengue virus 2 is required to produce DHF-like disease in immunocompromised mice after peripheral or intravenous infection. These mutations affect efficiency of viral replication or cell entry. A single amino acid change in NS4B modulates replicative efficiency, and two amino acid changes in the envelope protein affect interactions with heparan receptors for dengue infection.^{78,193,283} The operative correlate of vascular permeability is the inoculum dose of mouse-adapted dengue viruses. Using nonlethal virus concentrations, enhancing antibodies increase viremia, thrombocytopenia, liver disease, and vascular permeability. Recent studies tie these pathologic changes directly to cellular infection dynamics.

Epidemiologic evidence suggests the existence of a human dengue resistance gene. Epidemiologic studies of the 1981 Cuban outbreak demonstrated a higher risk for DHF/DSS in white than in black individuals.^{86,153} A search for DHF/DSS in black children in Haiti revealed no cases, despite the presence of high rates of dengue types 1, 2, and 4 infections and circulation of the Southeast Asian genotype dengue 2 viruses.¹¹⁵ Human leukocyte antigens and other genetic factors have shown differing frequencies in DHF/DSS cases and controls.^{51,231,243,244}

Early in the acute stage of secondary dengue virus infection, rapid activation of the complement system occurs.^{33,168} During shock, blood levels of C1q, C3, C4, C5, C6, C7, C8, and C3 proactivators are depressed and C3 catabolic rates are elevated. The blood clotting and fibrinolytic systems are activated.^{237,271,272} Studies find high levels of tumor necrosis

factor, interleukin-2, interleukin-10, and interferon- γ sometimes attributed to activated T lymphocytes or original antigenic sin, a phenomenon thought to direct pathogenic T-cell responses to cells infected with a second heterotypic dengue virus.^{154,173,212,224}

Two groups have shown that nonstructural protein 1 (NS1) of the dengue viruses are viral toxins that contribute to dengue pathogenesis by mechanisms analogous to those of bacterial endotoxins in the toxic shock syndrome.^{24,169} DENV NS1 activates the toll-like receptor 4 (TLR4) on primary human myeloid cells, resulting in increased production of proinflammatory cytokines and chemokines as a byproduct of this interaction. In both in vitro and in vivo models, DENV NS1 activates TLR4 on human and mouse endothelial cells, resulting in loss of endothelial integrity and vascular permeability. In early work, NS1 was shown to activate complement by the alternative pathway and to target liver cells promoting intracellular DENV infection, and it was detected as a complex with thrombin in acute-phase blood of dengue patients.^{2,17,160} The direct toxicity of DENV NS1 provides a single causal mechanism for the dengue vascular permeability syndrome, reconciling severe disease in infants born to dengue-immune mothers to that of older individuals experiencing a second dengue infection. It is still not understood why peak vascular permeability is delayed until defervescence rather correlating with peak NS1 blood levels observed earlier in disease.¹⁵⁸ It has long been suggested that the cellular immune response targeting dengue-infected cells triggers DVPS.⁹² But the failure of cortisone to prevent DVPS argues against a direct cytopathic role for cytokines and chemokines.²⁴⁶ It has been suggested that as dengue-infected target cells are disrupted by cytotoxic T cells, a final pathogenic bolus of DENV NS1 is released.

DIAGNOSIS

Dengue Fever

Activities of the patient during the period preceding the onset of illness may give important clues to the possibility of infection. The differential diagnosis includes many viral, respiratory, and influenza-like diseases and the early stages of malaria, typhoid fever, scrub typhus, hepatitis, and leptospirosis. Abortive forms of these diseases may never evolve beyond a DHF-like stage. At least five arbovirus diseases are similar to dengue: chikungunya and o'nyong-nyong fever (togaviruses), West Nile fever (flavivirus), Oropouche (bunyavirus), and Zika (flavivirus). Four other diseases are DHF-like but without rash: Colorado tick fever, sandfly fever, Ross River fever, and the mild form of Rift Valley fever. Many nonviral acute infectious diseases are DHF-like, malaria being number one. Because of the variation in clinical findings and the multiplicity of possible causative agents, the descriptive term *denguelike disease* should be used until a specific etiologic diagnosis is provided by the laboratory.

Dengue Hemorrhagic Fever, Dengue Shock Syndrome, and Severe Dengue

Children presenting with any warning sign should be hospitalized or placed under observation to initiate fluid resuscitation.¹² Using the DHF diagnostic algorithm, patients presenting with an acute fever plus complaints suggesting early cardiovascular collapse, thrombocytopenia ($<100,000 \text{ mm}^3$), liver enlargement, hemorrhagic manifestations, or a positive tourniquet test and suggestive hemoconcentration are hospitalized or placed under observation with fluid resuscitation.^{56,238} No matter which admission criteria are used, patients should be monitored to detect and quantitate vascular permeability. A research tool, strain-gauge plethysmography, was able to document microvascular permeability early and differentiate cases from controls.²⁵ However, repeated measurements of hematocrits are most frequently used to estimate hypovolemia by recording changes in hemoconcentration. Pleural or peritoneal effusions may be observed and fluid loss estimated using ultrasonography or radiography.²³⁸⁻²⁴⁰ New noninvasive diagnostic modalities are being investigated. Near-infrared spectroscopy has been used to measure muscle oxygen saturation as a correlate of vascular permeability.²³⁶ DSS is diagnosed when these manifestations are accompanied by hypotension or narrow pulse pressure ($<20 \text{ mm Hg}$).

In areas endemic for dengue, DHF/DSS or severe dengue should be suspected in children with a febrile illness who exhibit shock and

hemoconcentration with thrombocytopenia, hypoproteinemia, hemorrhagic manifestations, and hepatic enlargement. Because leptospirosis, many rickettsial diseases, meningococcemia, and other severe illnesses caused by a variety of agents may produce a similar clinical picture, the diagnosis should be made only when epidemiologic or serologic evidence suggests the possibility of dengue. Hemorrhagic manifestations have been described in other diseases of viral origin, including the arenavirus hemorrhagic fevers of Argentina, Bolivia, and West Africa (Lassa fever); the tick-borne hemorrhagic fevers of India and the former Soviet Union; hemorrhagic fever with renal syndrome, which occurs across northern Eurasia, specifically from Scandinavia to Korea; and Marburg and Ebola virus infections in Central and West Africa.^{59,139}

LABORATORY STUDIES

An etiologic diagnosis can be made by serologic study of properly collected serum samples, by isolation of the virus, and by identification of viral RNA or the nonstructural protein NS1 in acute-phase sera.^{85,277} The acute-phase serum or plasma collected for isolation of virus should be stored optimally at less than 65°C (149°F). Serologic diagnosis depends on a fourfold or greater increase in antibody titer by hemagglutination inhibition, complement fixation, radioimmunoassay, enzyme-linked immunosorbent assay (ELISA), or neutralization. Immunoglobulin M (IgM)-capture ELISA has revolutionized dengue serology, and commercial kits are available.^{31,32,132-135} Primary and sequential (secondary) dengue virus infections result in the production of dengue-reactive IgM antibodies, which appear during the acute phase and disappear within 60 days of infection.^{135,277} Secondary or primary dengue virus infections can be confirmed in a single serum specimen by quantitating IgM/IgG antibody ratios. IgG antibody concentrations are abundant in secondary but minimal in primary dengue virus infection. Dengue NS1 proteins can be detected in blood during the acute illness phase by dengue group-specific antibodies, and these have been formatted into commercial ELISA or rapid immunochromatographic tests.^{31,74,158,281} By combining IgM-capture ELISA and NS1 detection, point-of-care tests are available to diagnose acute dengue infections. Accurate use of diagnostic tests requires an understanding of the kinetics of primary and secondary dengue virus infections. Dengue IgM antibodies are seldom detected until 5 or more days after onset of fever. By contrast, dengue NS1 protein circulates in blood during and shortly after the febrile period, with higher detection in primary and secondary dengue infections.^{31,32}

Numerous techniques are available for the recovery and identification of dengue viruses.²⁷⁷ Recommendations for general use have been made by a WHO expert committee.²⁷⁷ Diagnostic testing for dengue virus infection is available through commercial reference laboratories, selected public health laboratories, and the Dengue Branch of the Centers for Disease Control and Prevention (<http://www.cdc.gov/dengue>). Acute-phase serum, mosquito suspensions, or other materials thought to contain dengue virus may be inoculated into suckling mice, which may be examined for sickness or subtle neurologic signs or challenged at 14 days with a neurovirulent dengue virus. Repeated subpassage markedly increases the neurovirulence of dengue virus. Alternatively, materials may be inoculated into any of several tissue cultures of mammalian or mosquito origin and examined for plaques under agar or methylcellulose overlay, for cytopathic effect, resistance to a challenge cytopathic virus by use of a fluid overlay, or fluorescence or other markers with the use of an appropriate detection system. Intrathoracic inoculation of *A. albopictus*, *A. aegypti*, or *Toxorhynchites* spp. is a highly sensitive dengue virus recovery system.^{206,209}

TREATMENT

Dengue Fever

Treatment is supportive. Bed rest is advised during the febrile period. Antipyretics or tepid sponging should be used to keep the body temperature below 40°C (104°F). Paracetamol ($10\text{--}15 \text{ mg/kg}$ every 4–6 hours), or acetaminophen, is the preferred antipyretic agent. Analgesics or mild sedation may be required to control pain. Fluid and electrolyte replacement therapy is required when deficits caused by sweating, fasting,

thirsting, vomiting, or diarrhea are present. Because of the potential for Reye syndrome and the dengue hemorrhagic diathesis, aspirin or other nonsteroidal antiinflammatory (NSAIDs) medications should not be given to reduce fever or to control pain. During dengue fever without detectable hypovolemia, adult patients may develop severe menorrhagia or gastrointestinal bleeding. Bleeding may be severe and require blood transfusions.

Outpatients With Mild Dengue Hemorrhagic Fever or Warning Signs

The Southeast Regional Office of the WHO has issued a special guideline for the diagnosis and management of dengue patients in small clinical facilities.¹⁰ In the absence of increased vascular permeability, clinically significant hemoconcentration may result from thirst, dehydration, fever, anorexia, and vomiting. Fluid intake by mouth should be as ample as tolerated. Electrolyte and dextrose solution (as used in diarrheal disease), fruit juice, or both are preferable to plain water. With high fever, a risk for seizures exists, so antipyretic drugs may be indicated. Salicylates should be avoided because they are known to cause bleeding and acidosis. Acetaminophen is preferable at the following doses: younger than 1 year, 60 mg per dose; 1 to 3 years, 60 to 120 mg per dose; 3 to 6 years, 120 mg per dose; and 6 to 12 years, 240 mg per dose.

Dengue Hemorrhagic Fever (Compensated Shock) and Dengue Shock Syndrome

Explicit recommendations for management of DHF (compensated shock), DSS, and severe dengue have been made by a number of international and national authorities.^{10,12-14} The 2009 WHO case definitions are widely accepted in the American hemisphere, whereas the 1997 WHO case definitions are still used in most of Asia. Despite these diagnostic differences, treatment in all cases focuses on the recognition and management of acute vascular permeability and is based on research observations.^{56,65,140,270}

Inpatients

Treatment of patients with Nonshock Dengue hemorrhagic fever (compensated shock). Critical care management of dengue vascular permeability syndrome is a major challenge to pediatricians because more than half of the world's children are at risk. Because dengue is a major disease of travelers, children experiencing dengue illnesses may present to any clinical care facility in the world. These children require that all pediatricians have access to detailed diagnostic and treatment guidelines and develop the skills to recognize and manage dengue shock, hemorrhage, and fluid overload (an all too frequent complication and cause of death). Basic treatment guidelines are given in this section. The reader is referred to authoritative texts, the most comprehensive being the 2012 WHO *Handbook for Clinical Management of Dengue*.¹²

A baseline hematocrit should be obtained. Immediate administration of intravenous fluid to expand plasma volume is essential. In children, shock may develop or subside during the course of a 48-hour period, so close observation 24 hours per day is imperative. Patients with similar degrees of severity should be grouped together. Those with shock require intensive 24-hour care by nurses and physicians. Paramedical workers or parents can assist in provision of oral fluid therapy or in surveillance of the rate of intravenous fluid administration and general status of the patient.

Treatment for patients with nonshock dengue hemorrhagic fever is as follows:

- Start intravenous fluid resuscitation with isotonic crystalloid solution at 5 to 10 mL/kg per hour over 1 hour. Then reassess the patient's condition (i.e., vital signs, capillary refill time, hematocrit, urine output).
- If the patient's condition improves, intravenous fluids should be gradually reduced to 5 to 7 mL/kg per hour for 1 to 2 hours, then to 3 to 5 mL/kg per hour for 2 to 4 hours, and then to 2 to 3 mL/kg per hour and then further depending on hemodynamic status.
- If vital signs are still unstable, check hematocrit after first bolus. If the hematocrit increases or is still high (>50%), administer a second bolus of crystalloid solution at 10 to 20 mL/kg per hour for 1 hour. After the second bolus, if there is improvement, reduce the rate to 7 to 10 mL/kg per hour for 1 to 2 hours. If the hematocrit decreases

from the initial reference hematocrit, this indicates bleeding. Immediately obtain cross-match and transfuse blood.

- Further boluses of crystalloid solutions may be necessary for the next 1 to 2 days.

Treatment of patients with shock. Treatment for patients with shock is as follows:

- For patients with narrow pulse pressure or systolic hypotension, initiate intravenous fluid resuscitation with crystalloid or colloid (gelatin has the least effect on blood coagulation, dextran 40 and 70 are in wide use) solution at 20 mL/kg as a bolus over 15 minutes to bring the patient out of shock as quickly as possible.
- If the patient's condition improves, give a crystalloid/colloid infusion of 10 mL/kg per hour for 1 hour. Then continue with crystalloid infusion and gradually reduce to 5 to 7 mL/kg per hour for 1 to 2 hours, then to 3 to 5 mL/kg per hour for 2 to 4 hours, and then to 2 to 3 mL/kg per hour or less, which can be maintained for up to 24 to 48 hours.
- If vital signs are still unstable, review the hematocrit obtained before the first bolus. If the hematocrit is low, this indicates bleeding and the need for blood transfusion.
- If the hematocrit was high in contrast to the baseline value, change intravenous fluids to colloid solutions at 10 to 20 mL/kg per hour as a second bolus given over 30 minutes to 1 hour. After the second bolus, reassess the patient. If the condition improves, reduce the rate to 7 to 10 mL/kg per hour for 1 to 2 hours, then change back to crystalloid solution and reduce the rate of infusion as mentioned earlier. If the condition is still unstable, repeat the hematocrit after the second bolus.
- If the hematocrit decreases from the previous value, this indicates bleeding and the need for blood transfusion. If the hematocrit increases from the previous value or remains very high, continue colloid solutions at 10 to 20 mL/kg per hour as a third bolus over 1 hour. After this dose, reduce the rate to 7 to 10 mL/kg per hour for 1 to 2 hours, then change back to crystalloid solution and reduce the rate of infusion as mentioned earlier.
- Further boluses may need to be given during the next 24 hours. The rate and volume of each bolus infusion should be titrated to the clinical response.

General management. If resources permit, patients with severe shock syndrome should have an arterial catheter placed. The reason for this is that in shock states, estimation of blood pressure using a cuff is commonly inaccurate. An indwelling arterial catheter allows for continuous and reproducible blood pressure measurements and frequent blood sampling on which decisions regarding therapy can be made. Monitoring of electrocardiogram and pulse oximetry should be available. Urine output should be checked regularly (i.e., hourly until patient is out of shock, then every 1 to 2 hours). Hematocrit should be monitored before and after fluid boluses until stable and then every 4 to 6 hours. In addition, there should be monitoring of arterial or venous blood gases, lactate, total carbon dioxide/bicarbonate every 30 minutes to 1 hour until stable, and blood glucose before fluid resuscitation and afterward as indicated.

Treatment of hemorrhagic complications.

- Patients in danger of bleeding are those with prolonged or refractory shock, hypotensive shock, and renal or liver failure or persistent metabolic acidosis; those who were given nonsteroidal antiinflammatory agents; those with preexisting peptic ulcer disease; those who are on anticoagulant therapy; and those who have any form of trauma, including intramuscular injections. Patients with hemolytic conditions are at risk for acute hemolysis with hemoglobinuria and will require blood transfusion.
- Severe bleeding can be recognized by refractory shock that fails to respond to consecutive fluid resuscitation of 40 to 60 mL/kg, hypotensive shock with low or normal hematocrit before fluid resuscitation, or persistent or worsening metabolic acidosis despite well-maintained systolic blood pressure, especially if accompanied by severe abdominal tenderness and distention.
- Give 5 to 10 mL/kg of fresh-packed red cells or 10 to 20 mL/kg of fresh whole blood at an appropriate rate and observe the clinical response.

- Consider repeating the blood transfusion if there is further blood loss or no appropriate rise in hematocrit after blood transfusion.
- There are no evidence-based data supporting the use of platelet concentrates or fresh-frozen plasma as a treatment for profound thrombocytopenia or severe bleeding. This treatment option is widely practiced in dengue-endemic countries and may contribute to fluid overload.

Recognizing fluid overload begins with knowing when to decrease or stop intravenous fluids. Intravenous fluids should be discontinued or reduced when there are signs of cessation of plasma leakage; stable blood pressure, pulse, and peripheral perfusion; hematocrit decreases in the presence of good pulse volume; no fever for more than 24 to 48 hours; resolving bowel and abdominal symptoms, and improving urine output.

Causes of fluid overload are excessive or too rapid intravenous fluids; incorrect use of hypotonic rather than isotonic crystalloid solutions; inappropriate use of large volumes of intravenous fluids in patients with unrecognized severe bleeding; inappropriate transfusion of fresh-frozen plasma, platelet concentrates, or cryoprecipitates; continuation of intravenous fluids after plasma leakage has stopped; and comorbid conditions, such as congenital or ischemic heart disease and chronic lung or renal disease.

Early clinical features of fluid overload are respiratory distress, difficulty in breathing, rapid breathing, chest wall retractions, wheezing (rather than crepitations), large pleural effusions, tense abdominal ascites, and increased jugular venous pressure.

Late clinical features are pulmonary edema (cough with pink or frothy sputum with or without crepitations; irreversible shock (i.e., heart failure with ongoing hypovolemia); the chest radiograph shows cardiomegaly, pleural effusion, upward displacement of the diaphragm by the ascites, and varying degrees of “bat wings” appearance with or without Kerley B lines suggestive of fluid overload and pulmonary edema.

Action plan for treatment of fluid overload. Treatment of fluid overload is as follows:

- Begin oxygen therapy immediately.
- Stop intravenous fluids.
- Check physiologic status: electrocardiogram to exclude ischemic changes and arrhythmia; arterial blood gases; echocardiogram for assessment of left ventricular function and regional wall dyskinesia that may suggest underlying ischemic heart disease; and cardiac enzymes.
- If necessary, give oral or intravenous furosemide 0.1 to 0.5 mg/kg per dose once or twice daily, or a continuous infusion of furosemide 0.1 mg/kg per hour. Monitor serum potassium and correct the ensuing hypokalemia.
- Patients who are in shock with low or normal hematocrit levels but who show signs of fluid overload may have occult hemorrhage. Further infusion of large volumes of intravenous fluids will lead only to a poor outcome. Careful transfusion of fresh whole blood should be initiated as soon as possible. Repeated small boluses of colloid solution may be helpful.

REGULATORY MEASURES

Dengue diseases are not subject to international quarantine or surveillance regulations. Dengue is a nationally notifiable disease in the United States, and suspected cases should be reported to the local health department. An intensive and effective voluntary reporting system has been devised by the regional offices of the WHO. People traveling to areas where dengue is endemic should assess the risk (<http://www.healthmap.org/dengue/>) and take necessary precautions to protect themselves against mosquito exposure.

PROGNOSIS

Not all patients suspected of having DHF need to be hospitalized because circulatory failure and shock may develop in only approximately one-third of patients. Mild and moderate cases may be treated on an outpatient basis. For the purpose of early recognition of shock, parents should be advised to bring the patient back if evidence of clinical deterioration

is noted or such warning signs as restlessness with or without lethargy, severe abdominal pain, cold extremities, and skin congestion occur on or after the third day after the onset of fever.

In most cases, early and effective replacement of lost plasma with plasma, plasma expanders, or fluid and electrolyte solutions (or any combination of these products) results in a favorable outcome. The acute onset of shock and the rapid, often dramatic clinical recovery, together with the fact that no destructive or inflammatory vascular lesions are observed, suggest that the disease is produced by transient functional vascular changes caused by short-acting pharmacologic mediators.

Sequelae in dengue and DHF have not been studied systematically. Common sequelae of mild and uncomplicated dengue virus infection include bradycardia and ventricular extrasystoles during the convalescent stage, often persisting for several weeks. Profound asthenia with or without mental depression has been described. In patients with DHF/DSS, great care must be taken to reduce use of invasive procedures for managing shock. Nosocomial infections such as gram-negative sepsis can masquerade as DHF/DSS. Overhydration during the shock resuscitation phase may lead to heart failure and a complicated, stormy postshock stage. Infrequently, residual brain damage occurs, apparently as a result of either prolonged shock or, occasionally, intracranial hemorrhage. Children in whom profound shock develops rapidly with no detectable diastolic pressure or with unobtainable blood pressure, children in shock with delayed admission to the hospital, or children in shock with gastrointestinal hemorrhage have a poor prognosis. Mortality rates may exceed 50% in these groups.

PREVENTION

Three immunogenic tissue culture–based vaccines containing antigens for dengue virus types 1, 2, 3, and 4 are in phase III human clinical trials. A vaccine now licensed in 16 countries, manufactured by Sanofi Pasteur, is a chimera of the nonstructural genes of yellow fever 17D vaccine spliced with structural genes of the four dengue viruses.⁸⁴ It is designed as a two-dose vaccine to be given at months 0, 6, and 12 to individuals 9 to 45 years of age who have overall prevalence of dengue antibodies of 70%. This vaccine has received endorsement from the WHO.^{15,89,116} This vaccine is not designed for, nor available for use by, tourists to protect against dengue infection. Another vaccine, comprising one chimeric and three mutagenized dengue viruses, was designed by the US National Institutes of Health and licensed to Merck, as well to several dengue endemic country vaccine manufacturers.⁶⁷ In human challenge studies, this vaccine has been shown to be highly protective.¹⁴⁸ A final vaccine, developed by the Centers for Disease Control and Prevention, was licensed to Takeda Pharmaceuticals and comprises chimeras of dengue 2 virus.^{189,190}

Today, for most at-risk countries, prophylaxis depends on killing vector mosquitoes or avoiding mosquito bites. This involves the use of insecticides, repellents, protective body clothing, and screens on houses to avoid mosquito bites. Destruction of *A. aegypti* breeding sites also is effective. The WHO issues definitive guidelines with technical information and advice on organizing national vector control programs.^{11,14,277} If water storage is mandatory, a tight-fitting lid or a thin layer of oil may prevent eggs from being deposited or hatching. A larvicide such as temefos (Abate), which is available as a 1% sand granule formulation and effective at a concentration of 1 ppm, may be added safely to drinking water.

Epidemic Measures

The WHO recommends integrated vector management, which requires training, preparation, and application of appropriate technologies.²⁷⁷ Control of *A. aegypti* is mainly achieved by eliminating container habitats that are favorable oviposition sites, permitting development of aquatic stages. In emergencies, space sprays can be applied either as thermal fogs at 10 to 50 L/hectare or as ultra-low-volume applications of undiluted or slightly diluted technical-grade insecticide in the form of a cold aerosol or droplets of controlled size (15–25 μm) at a rate of 0.5 to 2 L/hectare. Portable or vehicle-mounted thermal or cold-fog generators can be used for ground application. If the target area exceeds

1000 hectares or cannot be covered for ground equipment within 10 days, aerial cold fog application is sometimes used. Applications vary with the susceptibility of the target species and environmental conditions, such as wind speed. Cold-fog applications from large fixed-wing aircraft are made at approximately 240 km/h and 60 m above the ground.

Eradication and Control

A. aegypti was eradicated successfully from countries and whole continents with use of the techniques pioneered by the Rockefeller Foundation in its worldwide program to control urban yellow fever.^{82,245} An eradication campaign in the United States was abandoned and replaced by a program of disease surveillance and containment of introduced virus. After 1970, the species successfully reestablished itself in much of its former range. Mosquito control or eradication programs require the simultaneous use of two approaches: a reduction in breeding sites and the application of larvicides. Alternatively, a significant reduction in population may be effected by closely spaced applications of adulticide.^{79,80} Vehicle-mounted or portable ultra-low-volume aerosol generators or mist blowers can be used to apply technical-grade malathion or fenitrothion at 438 mL/hectare. Three applications made at 1-week intervals can suppress *A. aegypti* populations for approximately 2 months.

Source reduction requires public support by either legal sanctions or voluntary actions (see the following section). Source reduction campaigns should be well organized, supervised, and evaluated. Proper disposal of discarded cans, bottles, tires, and other potential breeding sites not used for storage of drinking or bathing water should be performed. Sides of water storage containers should be scrubbed to remove eggs when the water level is low. Water storage containers for drinking and bathing and flower vases should be emptied completely once weekly. Water containers that cannot be emptied should be treated with Abate 1% sand granules at a dosage of 1 ppm (e.g., 10 g of sand to 100 L of water). Treatments should be repeated at intervals of 2 to 3 months.

In dengue-endemic countries, little effort has been made to adopt building codes or waste collection methods to reduce the number of mosquito breeding sites.¹⁵⁶ Furthermore, almost no way has been found to use the resources and skills of the private sector to implement vector control despite ample evidence of long-term successful vector mosquito abatement programs in the United States.^{47,55}

New generations of vector control methods are under active development and testing. *Mesocyclops*, an antilarval insect predator, has been introduced into water storage containers in rural Vietnam with near eradication of *A. aegypti* larvae.^{145,146,233,259} Infection of *A. aegypti* by *Wolbachia*, a species of rickettsial-like organism, blocks replication of dengue virus and vectoral capacity of the mosquito.^{121,185,261} *Wolbachia* has been successfully introduced into wild populations of *A. aegypti* with sufficient spread to prevent dengue transmission.^{41,180,203,247} Various methods of achieving and spreading sterile *A. aegypti* males or flightless females are being tested in the field.^{69,75,119,275,276} Autocidal mosquito traps may be effective in areas of recent mosquito introduction or low, dispersed populations.²³

Health Education

Control of *A. aegypti* has been maintained effectively in some tropical areas through the simple expedient of emptying water containers once per week. During the yellow fever campaigns, strong sanitary laws made the breeding of mosquitoes on premises a crime punishable by fine or jail.²⁴⁵ In the modern era, Singapore and Cuba have adopted these measures with moderate degrees of success.¹⁸⁸ Health education through mass media and schools has been attempted in Myanmar, Thailand, Malaysia, and Indonesia, but without spectacular success.⁶⁴ The goals of health education and community participation approaches are to make the population aware of the identity of the vector of DHF, to describe its biting habits (daytime feeding) and its breeding habits (containers holding clean water), and to motivate people to reduce breeding sources by emptying water from containers on a regular basis.^{8,273,274} The use of piped water rather than water storage should be encouraged. Studies in Malaysia after the 1973 epidemic of DHF indicated a very low level of functional knowledge among the inhabitants of Kuala Lumpur, Malaysia, about the vector of DHF.⁶⁴ Discouragingly, persons who were informed correctly, in most instances, took no action to protect themselves against mosquito breeding in their homes. Extensive effort is being made to

apply social science methods to gain the voluntary participation of the population in sustained mosquito control programs.^{8,161}

176E ■ Japanese Encephalitis

Theresa Barton

Japanese encephalitis (JE), a mosquito-borne flavivirus infection, is the leading vaccine-preventable viral encephalitis in Asia.

HISTORY

JE first was recognized after an outbreak in Japan in 1924 led to an alarming 6125 cases of encephalitis. In retrospect, similar summer and autumn outbreaks were recognized as early as 1871 to 1873.^{28,43} In 1933, Hayashi recovered the virus from monkeys and the brain of a patient, and in 1938, Mitamura confirmed its mosquito-borne mode of transmission by isolating the virus from *Culex tritaeniorhynchus*.⁴³ An inactivated vaccine was licensed in Japan in 1956, and its use successfully controlled

the disease in Asian countries where it was deployed. New inactivated cell culture–derived and live, attenuated vaccines are now displacing the efficacious but reactogenic 50-year-old mouse brain–derived product.³³ Despite preventative measures, JE causes 15,000 deaths per year and continues to evolve in new geographic regions.¹¹ It is considered a neglected tropical disease despite its impact.

ETIOLOGIC AGENT

JE virus is a member of the flavivirus antigenic complex that includes St. Louis encephalitis, Murray Valley encephalitis, and West Nile viruses. Five viral genotypes have been described. Since the 1980s, viruses in

genotype I have displaced previously predominant genotype III strains, and genotype V viruses also may be emerging.^{16,17,58,79,113} Because humans are incidental to the viral transmission cycle, the changing distribution of viral genotypes indicates evolving viral adaptation to vertebrate hosts and mosquito vectors responsible for viral maintenance. However, the virus exists as a single serotype, and all vaccines are made from genotype III strains, with no evidence that they fail to prevent disease caused by viruses in other genotypes. Genotypic strains were previously associated with distinct geographic distribution, but subsequent observations have shown shifts in genotype presence within areas.^{87,97}

As with other flaviviruses, important biologic functions, including attenuation and viral neutralization, are associated with the E glycoprotein. With repeated cell culture passage, biologically derived neuroattenuated strains have been produced for use as vaccines.¹¹¹ Combinations of mutations in genes of the E protein, nonstructural proteins, and noncoding regions have been associated with attenuation of the live vaccine strain SA 14-14-2 and so have been selectively incorporated with others into a chimeric JE vaccine using nonstructural proteins from the itself attenuated yellow fever 17D vaccine strain.³³

JE virus is perpetuated in both wild, or sylvatic, and domestic cycles. JE mosquito vectors are largely opportunistic, feeding on numerous available hosts.¹⁰⁵ JE virus is transmitted between birds and *Culex* mosquitoes; however, pigs, when present, are the most important source of viral amplification (Fig. 176E.1).^{3,5,93,94} This domestic cycle of JE is the most important source for human disease. Domestic pigs maintain high sustained viremias and may be hosts to thousands of mosquitoes in a single night, thereby serving as prolific sources of infected vectors capable of transmitting the virus onward. In rural Asia, the onset of human cases each summer occurs shortly after pigs become infected, following which the epidemic curves of human and pig infections evolve in parallel.⁸² However, outbreaks of JE have occurred in areas devoid of pigs, where birds, including ducklings, pigeons, sparrows, and possibly other small birds found near human residences, have served as amplifying hosts.^{3,5,29,93}

In the sylvatic cycle vectors transmit to mammalian reservoirs, with bats and peridomestic wild mammals such as wild boar and raccoons playing an integral role.^{55,75} The bird-associated sylvatic cycle is crucial to viral persistence in the environment as well as spread of the virus

to new geographic areas.⁵ More than 90 bird species can amplify and serve as viral reservoirs. Wading birds such as egrets and herons are particularly effective reservoirs with high viremia and ability to infect vector mosquitoes.¹⁰⁵

C. tritaeniorhynchus is the major mosquito vector in most areas of Asia, and distribution in niches below 1000-m elevation (valleys in Tibet and Kathmandu are conspicuous exceptions), along with other environmental and climatic features, corresponds well to the distribution of human cases.^{70,94} That distribution also overlaps the land cover used for rice paddies. *C. tritaeniorhynchus* exploits ground pools and especially rice paddies in its preadult stages, emerging in immense numbers from the flooded rice paddies responsible for 80% of the land cover in some areas and that frequently surround individual residences and villages. The vector is zoophilic and prefers to feed on large animals such as pigs and less so on humans, but with the custom of keeping pigs near or inside houses in rural Asia, residents live in the midst of the viral transmission cycle and are at high risk for exposure to infected mosquitoes, starting at an early age. Living in proximity to a rice field and pig ownership understandably are risk factors for acquiring the illness.⁶⁴ Although *C. tritaeniorhynchus* is most active in the evening and night, because adults feed outdoors, bed nets are not entirely protective.

In various regions, other species (*Culex pseudovishnui*, *Culex vishnui*, *Culex gelidus*, *Culex fuscocephalus*, *Culex annulirostris*, and *Culex bitaeniorhynchus*) with different habitats may also serve as vectors.^{3,94} Anopheline mosquitoes may contribute to transmission in northeastern India. The viral overwintering mechanism for JE virus has been a matter of speculation; however, vertical infection of mosquito eggs has been demonstrated as a means by which transmission is reestablished.^{25,94}

Ecologic factors have been modeled to describe the seasonality of infection and to predict the occurrence and severity of outbreaks; surveillance tools include monitoring infections in pigs, birds, dogs, and horses, as well as precipitation and temperature. The potential impact of global climate on JE seasonality has been speculated because warmer environmental temperature shortens the extrinsic incubation period of related flaviviruses, thereby speeding the transmission cycle. In support of this hypothesis, a secular trend toward an earlier onset of JE transmission in Taiwan has been noted, from June to May, whereas

FIGURE 176E.1 Transmission cycle of Japanese encephalitis virus. Speculative portions of the cycle are shown in broken lines.

high summertime temperatures have been associated with the occurrence and severity of West Nile and St. Louis encephalitis outbreaks.

EPIDEMIOLOGY

JE is the largest worldwide cause of epidemic viral encephalitis.¹⁰ Approximately 68,000 JE cases occur annually, causing about 10,000 to 15,000 deaths across Asia and the Australian continent. In areas where children are not routinely vaccinated, cases occur mainly in children after the first year of life, with a slight preponderance in boys. More than 99% of infections are subclinical, and cumulative exposure with age leads to seroprevalence rates of 80% or more by adulthood.³¹ In Japan and other developed Asian countries, where children are protected by routine vaccination, adult cases now predominate.^{2,50,57} A majority of cases occur in adults older than 45 years, because of immunosenescence and age-related chronic diseases that may be risk factors. Waning protection from remote childhood vaccination may also be shifting epidemiology to adult disease.⁴²

Transmission is seasonal, during late summer and early fall in temperate regions (July to October) and over a longer interval in tropical and subtropical regions, such as southern China and Southeast Asia (April to November).¹¹³ Mosquitoes proliferate after monsoon rains, and multiple epidemic seasons or year-round transmission is possible in some tropical locations. In many locations, vector populations now follow irrigation-controlled schedules of rice field flooding and other patterns dictated by mechanized rice production rather than the traditional rainy season.⁷⁸

JE transmission is endemic in nearly every country in Asia (Fig. 176E.2).¹¹ Annual incidence rates range widely from less than 0.01 to 5 per 100,000, depending on vaccine coverage and environmental conditions, and epidemic attack rates as high as 100 per 100,000 have been described.¹⁰⁶ Incidence is underestimated because the unavailability of laboratory confirmation limits specific diagnosis and surveillance. In addition to seasonal epidemics, self-limited outbreaks can occur after the virus is introduced by migrating birds or other mechanisms, coupled with unusual conditions of human activity or weather patterns, but transmission is usually not sustained after the exhaustion of susceptible hosts.^{35,80} Few cases are reported from countries where vaccination rates are high (e.g., Japan, Korea, and Taiwan) and where development through urbanization, decreased agricultural land use, and improved

standards of living have reduced human exposure. The use of agricultural pesticides and centralized pig rearing also may have contributed to lowering risk. Although the number of human cases has decreased in some areas, enzootic animal transmission persists. Horses can develop encephalitis, and outbreaks and economically significant loss of prize horses have led to routine use of equine vaccines in China, Mongolia, and Japan. Sows also are vaccinated, not to prevent illness in the animals, which remain asymptomatic after infection, but to prevent congenital infection of piglets, which may die in utero or may be born with lethal neurologic malformations. For example, in Japan, more than 80% of pigs and 2.6% of the human population still are infected each year.^{2,51} Domestic animals such as dogs and cattle can be infected, but their viremias are insufficient to support further transmission. Because they are attractive hosts to JE vectors, they may divert mosquitoes from humans, thereby protecting them from infection (zoonophylaxis).

Although economic development has paralleled a decline in JE, in some areas, development in the form of deforestation, construction of dams, and irrigation schemes has led to increases in transmission of JE virus or its emergence in areas where the disease had not occurred previously. Examples include development projects in the Terai in southern Nepal and the Mahaweli Valley in Sri Lanka, where JE and malaria have become hyperendemic after large-scale programs of deforestation and agricultural development.

Travelers to areas where JE is endemic may be at risk for acquiring the illness.³⁷ Updated information can be obtained from the Centers for Disease Control and Prevention (CDC) at the website <http://www.cdc.gov/travel/>. Approximately 80 cases have been reported in travelers and expatriates (including military personnel and their family members) from North America, Europe, Russia, and Australia in the past 20 years, but the number undoubtedly is larger because of under-reporting.³⁷ The risk for acquiring the disease can best be described as serendipitous—cases have been reported in travelers who were infected within days of arriving in Asia, who never visited a rural area, and who had none of the risk issues cited in recommendations. The generally low but difficult-to-predict risk can be understood by factoring the probability of development of an illness after a single mosquito bite—only certain vector species transmit the virus, typically less than 3% of vector mosquitoes are infected, and only one in several hundred infections leads to clinical illness. Other factors entering into the risk for acquiring infection and illness are described in Table 176E.1.

FIGURE 176E.2 Clinical stages of a typical Japanese encephalitis case.

TABLE 176E.1 Factors to Consider in Recommending Japanese Encephalitis (JE) Vaccine for Travelers to Asia

Factor	Comment
Expatriates	During extended assignments, expatriates likely will make unanticipated trips within the region, including to areas where the risk for acquiring JE is high or unknown.
Visiting friends or relatives	Returning families may be more likely to visit ancestral villages or other locations that pose a greater risk for viral transmission. Parents may have been vaccinated or have acquired natural infections before they emigrated and may not realize that their own children are unprotected.
Travelers with open itineraries	"Year abroad" and other travelers who have open itineraries may journey to locations where risk for disease is higher, including rural areas.
Frequent travelers	Travelers who have second homes in the region or who travel frequently to Asia, even if individual trips are brief, have a cumulative risk for exposure.
Season	In East Asia, which has a temperate or subtropical climate, transmission usually is described as extending from April to October, but within individual countries even the size of Thailand, transmission periods may differ by several months from north to south, or, as in China, from West to East. In the tropical zone, the virus may be transmitted year-round with superimposed patterns of higher risk. In many locations, seasonal monsoons dictate the periods when mosquito vectors are prevalent, and those patterns can differ within surprisingly delimited geographic bounds, such as for Southeastern versus Southwestern India. Historical seasonal patterns may not be predictive in any given year. As rice cultivation has become more industrialized, the timing of rice field flooding and resulting blooms of vector mosquitoes may not correspond only to natural patterns of rainfall.
Activity out of doors	Persons with extensive occupational or recreational outdoor activities, especially at twilight and evening, are more likely to be exposed to the principal JE mosquito vectors. Even brief episodes outdoors (e.g., an elephant ride) have been reported in case histories of travel-associated JE.
Exposure to vector mosquito habitat	Most recommendations cite "rural exposure" as a risk factor for acquiring JE. However, "rural" is used in this context as a proxy for exposure to rice paddies that are highly productive habitats for JE vectors. Rice paddies, however, are found at the edges or even within major Asian cities (e.g., in Denpasar, Indonesia, the city greenbelts are rice fields). Moreover, other pools of water (e.g., flooded ditches) can support species capable of transmitting JE virus; thus infected mosquitoes and seroconverting sentinel animals have been detected in urban or suburban surveillance sites.
Exposure to pigs	Pigs are highly important in amplifying JE virus in the usual transmission cycle. Although locations with few or no pigs may pose a lower risk for encountering virus-infected mosquitoes, birds, ducks, and potentially other vertebrates also can amplify the virus and have been implicated in outbreaks.
Age	Infants and older adults are at an increased risk for developing neurologic disease after infection, in contrast to young adults.
Chronic disease	Immunocompromising conditions, including HIV infection, increase risk for illness. Other chronic diseases, including cardiovascular disease, hypertension, and metabolic conditions, have been associated with risk for illness or increased severity of illness for other flaviviruses. Because observational and experimental data indicate that certain underlying neurologic diseases (e.g., neurocysticercosis and other concurrent neurologic infections) can facilitate neuroinvasion, it seems possible that CSF shunts, cochlear implants, baclofen pumps, and other implanted devices, as well as other neurologic disorders, could pose a similar risk.
Pregnancy	JE acquired in pregnancy has been associated with miscarriage and fetal death. However, no safety or immunogenicity data in pregnant women are available on use of the only available JE vaccine in the United States, an inactivated cell culture–derived vaccine (Pregnancy Category B). Pregnancy is a precaution for vaccination, and vaccination in pregnant women should only be done when there is a clear risk for infection.
Genetic factors	Several studies suggest that persons homozygous for <i>CCR5Δ32</i> are at increased risk for clinical illness from the flaviviruses, West Nile virus and tick-borne encephalitis virus. This deletion is so uncommon in Asia that it is unlikely to be unimportant as a risk factor among the indigenous population; however, it is a consideration for persons with other ancestries.
Concurrent medication	Immunosuppressant medications may reduce response to vaccination. Coadministration of hepatitis A vaccine does not reduce immunogenicity. Coadministration with other vaccines has not been studied. It is recommended to give concomitant vaccines at different sites using different syringes.
Vaccine safety	The inactivated Vero cell–derived vaccine available in the United States is well tolerated and has not been associated with any safety issues since its licensure in the United States, Europe, and Australia in 2009. Clinical trials demonstrated serious adverse events in 1% of recipients. Minor side effects occurred in 40% of children and 59% of adults. The most commonly reported side effects were injection site reactions, headache, flulike illnesses, diarrhea, and low-grade fever.
Vaccine cost	Travel vaccines are generally not reimbursed by health insurance schemes, so the decision to take the JE vaccine is a decision for an out-of-pocket discretionary "purchase." Therefore highly personal factors and perception of risk should be explored and respected when advising travelers regarding vaccination.

CLINICAL MANIFESTATIONS

The majority of JE infections are asymptomatic or manifest as mild self-limited illnesses. Occasional cases of JE viremia are identified in serologic studies of children with undifferentiated fever, which might otherwise have been diagnosed clinically as dengue or another viral syndrome. However, patients who develop neurologic infection usually are profoundly ill, and 5% to 25% of cases are fatal. After an incubation period of 4 to 14 days, the illness begins with lethargy, nausea or abdominal pain and vomiting, headache, and fever (Fig. 176E.3).^{4,52,53,61,92} The prodrome is followed by increasing lethargy or changes in behavior

and motor disturbances over several days, leading eventually to impaired consciousness and coma. The initial presentation varies, however; in some cases, it may be a sudden seizure, whereas in others, there may be a long prodrome of a week or more, with periods of confusion or agitation and unsteadiness of gait and other motor abnormalities. Unusual manifestations, such as acute psychosis and Guillain-Barré syndrome, also have been reported.⁹⁰

The principal physical findings are high fever and alterations in consciousness, ranging from mild mental clouding, frank disorientation, and delirium, to coma. Some children exhibit bizarre behavior, including mutism, shouting, spitting, and personality changes. Signs of meningeal

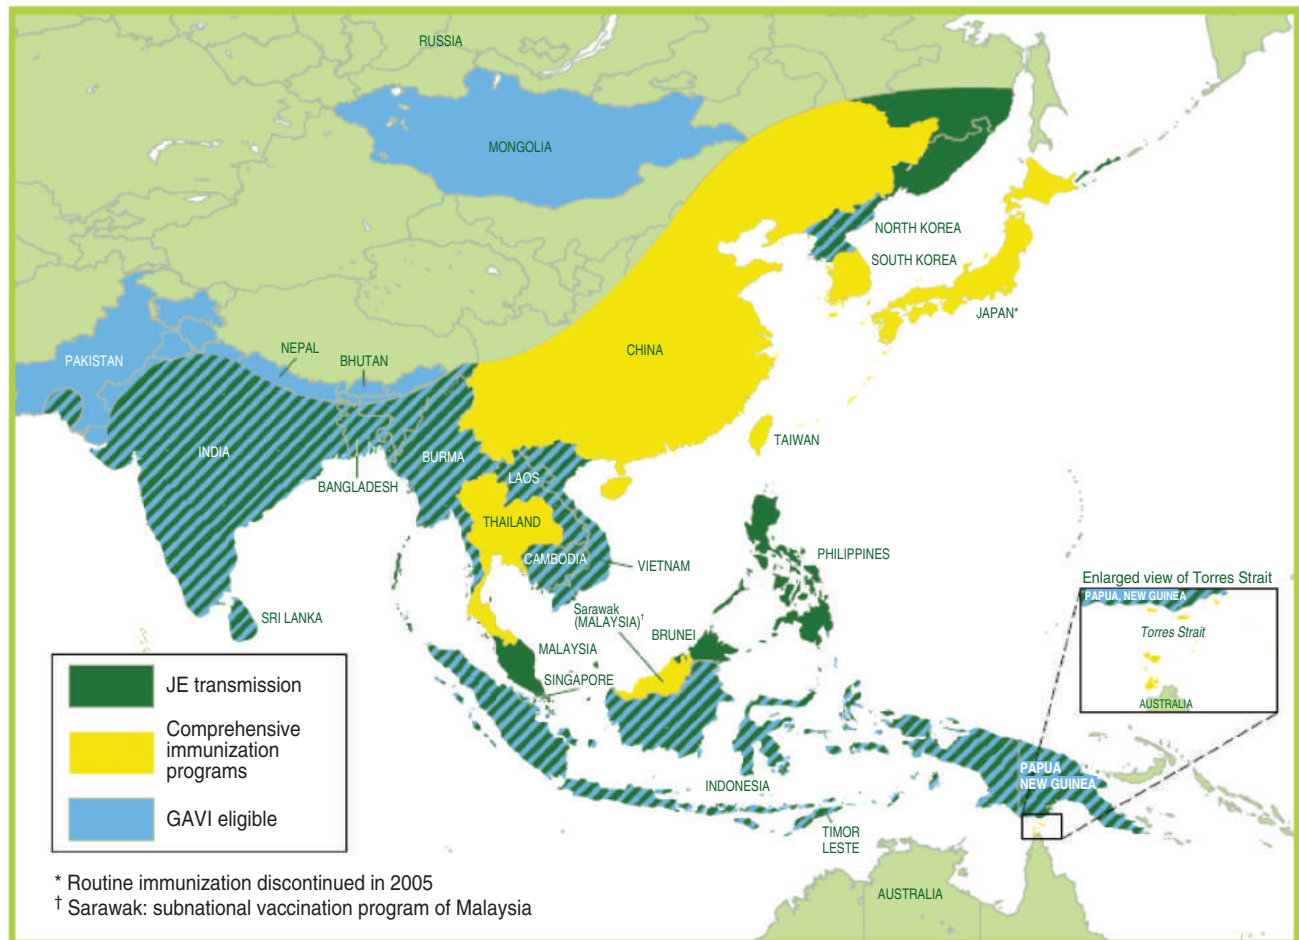

FIGURE 176E.3 Locations where Japanese encephalitis (JE) is prevalent.

irritation are present. Cranial nerve palsies, mainly disconjugate gaze and central facial paralysis, are observed in one-third of cases, and generalized or focal motor weakness can usually be demonstrated, presenting with either flaccid or spastic paralysis. Some patients exhibit erratic flailing movements, tremor, rigidity, expressionless facies, or thick slurred speech; frequently, choreoathetosis and other extrapyramidal signs become evident only in the second week of illness. Focal or generalized seizures develop in 50% to 75% of patients. Papilledema is seen in 10% of cases, along with hypertension, indicating increased intracranial pressure. In more than one-third of patients, coma and respiratory failure necessitate ventilatory support. Patients with fulminant infections may die within the first 5 days of illness.

Recovery is slow, with defervescence of fever followed by gradual improvement of neurologic function over several weeks. During convalescence, stasis ulcers, urinary tract infections, pneumonia, and bacteremia may complicate the course. In anecdotal cases, a biphasic pattern of illness has been described, with a recurrence of motor and behavioral abnormalities 2 to 5 weeks after initial improvement, accompanied by larger and more numerous associated lesions on magnetic resonance imaging (MRI).⁶⁹ Recovery of motor function and adaptation to sequelae may progress over a period of months to years.

Routine laboratory studies initially show a peripheral leukocytosis, often with bandemia. Opening pressures on lumbar puncture usually are normal or slightly elevated. Cerebrospinal fluid (CSF) pleocytosis ranges from fewer than 10 cells to several thousand, with a median of several hundred per cubic millimeter, potentially leading to a misdiagnosis of bacterial meningitis. Lymphocytic pleocytosis follows, and CSF glucose and protein levels frequently are normal (80% of cases); when elevated, protein levels rarely exceed 100 mg/dL.

Electroencephalograms typically show diffuse theta to delta wave slowing, whereas spike and wave discharges are relatively uncommon.

MRI is more sensitive using T2-weighted and fluid attenuation inversion recovery (FLAIR) sequences in early stages of illness, with a relatively lower sensitivity from diffusion-weighted signals.^{34,69} A distinct pattern of hyperintensity in the thalamus, basal ganglia, and brainstem has been noted, although cortical, cerebellar, and spinal cord involvement is seen. Electromyograms show a neurogenic pattern consistent with anterior horn cell involvement.¹⁰¹ Central motor conduction times are prolonged, indicative of diffuse subcortical damage.

PATHOLOGY

Although JE presents clinically as a central nervous system (CNS) infection, often overlooked is that the infection is pantropic, with pathologic changes found in the lungs and viscera, in addition to the brain.^{23,24,39,44,59,99,114} On gross examination, the brain appears swollen and the meninges may be congested with macroscopically visible punctate hemorrhages. Microscopic examination discloses a moderate inflammatory response in the meninges. The parenchyma shows foci of neuronal degeneration and parenchymal and perivascular inflammatory responses principally in the thalamus and brainstem, but also more widely, in the hippocampus, temporal cortex, cerebellum, and spinal cord. Areas of neuronophagia may be surrounded by microglial nodules, but sharply defined round areas of softening or necrosis without an inflammatory response also are seen. Purkinje cells and cerebellar glial shrubs also may be lost.¹¹⁴

PATHOPHYSIOLOGY

After virus is introduced by a mosquito bite, replication within regional lymphatic tissue leads to a secondary amplified viremia and disseminated infection that includes the CNS. Neuroinvasion is thought to occur through

cerebral capillaries as virions cross from the vascular side of the endothelial cell to the perivascular space, with subsequent neuronal infection, or by infected inflammatory cells crossing the blood-brain barrier. Neurons show evidence of viral antigen in the cell body, axons, and dendrites, indicating cell-to-cell viral spread within the brain.^{22,23,48,58} CSF levels of catecholamines and their metabolites are acutely lowered.³⁹ Infiltrating T cells elicit a broad inflammatory response, with B cells, T cells, and macrophages found in perivascular cuffs and macrophages and T cells in the parenchyma.^{48,109} Neuronophagia proceeds with the formation of microglial nodules and the eventual disappearance of neurons, leaving ghostlike remnants with antigen accumulated within macrophages.

Relatively low levels of circulating neutralizing antibodies, approximately 1:10, correlate with protection, and the rapidity of the neutralizing antibody response in naïve individuals is a principal determinant of outcome.^{8,9,48,74} Most fatal cases occurring within approximately 5 days after the onset of illness have no detectable CSF antibody response while virus is recoverable from the CSF, indicating unimpeded viral replication.^{8,9} In experimentally infected animals, passive immunization reduces mortality, even when it is given 4 to 5 days after inoculation.⁷⁴ However, the persistence of viral antigen in neurons for extended periods in the presence of intrathecal antibody and immune complexes in some cases, and development of antineurofilament antibodies, indicate the importance of viral clearance and potential for immunopathology in delayed or incomplete resolution of illness.²²⁻²⁴ The role of innate immune responses is not well characterized, but they may contribute to both control of infection and immunopathology.^{104,109} The contribution of interferon and CCR5 ligands in susceptibility may be inferred from studies of other flaviviral infections that associated risk with oligoadenylate synthetase polymorphisms and CCR5Δ32 gene deletions.^{9,60} Elevated CXCL8 levels in serum and CSF have been associated with increased disease severity and duration.

Why most JE virus infections are subclinical or lead to no signs of infection in the CNS is unclear. Epidemiologic observations indicate an elevated risk for JE in elderly people and increased severity in young children, but the biologic basis for age-related susceptibility remains poorly understood. Tumor necrosis factor- α promoter polymorphism also has been suggested as a specific risk factor.⁸⁶ Pathologic observations have shown a higher prevalence of neurocysticercosis in fatal JE cases than in deaths from other causes, which suggests that physical or physiologic disruption of the brain architecture by infection or other mechanisms could facilitate neuroinvasion.^{20,63,101} Experimental dual infection of animals with JE virus and other agents supports this hypothesis. In experimental animals, other host factors associated with a risk for acquiring illness and poor outcome include flavivirus-specific susceptibility genes, age, levels of sex hormones, and cold and stress responses. Because dengue infections are prevalent across much of the JE-endemic region, the role of cross-reactive flavivirus immunity in the clinical outcome of JE is of considerable interest; unfortunately, no clear pattern of protection or increased risk has been confirmed.^{1,27}

COMPLICATIONS

The principal risk is secondary bacterial infection occurring in the acute and subacute phases of illness. In addition, concurrent malaria and other parasitic or bacterial infections that are endemic in Asia may complicate management. Although JE occurs in areas of Asia where human immunodeficiency virus (HIV) infection is prevalent, data are insufficient to conclude differences in outcome in coinfecting patients. Hyponatremia caused by inappropriate antidiuretic hormone secretion also can complicate treatment.

Cases of clinical relapse with seizures, coma, and weakness, several occurring 6 to 9 months after recovery from the acute illness, have been reported.^{85,89} These and other patients experiencing relapse had evidence of persistent JE virus infection in peripheral blood mononuclear cells.¹⁰⁰ A study of 253 patients found laboratory evidence of subacute CNS infection in 5% of cases, with persistent intrathecal production of JE virus-specific immunoglobulin M (IgM) beyond 50 to 180 days or CSF containing JE virus antigen or virus more than 3 weeks after recovery.⁸⁹ These observations suggest that some infections may be followed by viral persistence, but additional confirmatory studies are needed.

JE acquired during the first two trimesters of pregnancy may lead to fetal infection and miscarriage, which has been confirmed by viral isolation from products of conception in a few cases.^{15,67} Infections acquired during the third trimester, however, have not been associated with adverse outcomes to the pregnancy. It is still unknown whether sublethal malformations can result from congenital infection and whether subclinical infections acquired during pregnancy pose a risk for fetal infection. Because JE virus is a proven teratogen in pigs, producing fetal death and CNS malformations, there is a need for closer studies in humans.^{2,3,10}

LABORATORY DIAGNOSIS

A specific diagnosis can be made serologically by identifying JE virus-specific IgM antibody in serum or CSF by enzyme-linked immunosorbent assay (ELISA); often, however, results need to be confirmed by demonstrating fourfold titer changes in neutralizing antibodies between acute-phase and convalescent-phase serum samples to resolve cross-reactions to dengue and other flaviviruses.⁶⁶ Several IgM detection kits exhibiting good sensitivity and specificity are commercially available.^{71,88} IgM can be detected in serum or CSF (or in both) in nearly all cases by 1 week after the onset of illness. Although real-time polymerase chain reaction (PCR) and reverse transcriptase loop-mediated isothermal amplification (RT-LAMP) assays have been described, their limited availability in the endemic situation has limited opportunities for evaluation.²¹ Available reports indicate that as a result of the sensitivity of these methods, both acute serum samples and CSF should be tested because viremia may be detected early in infection in the preneuroinvasive phase of illness, although usually no later than 6 to 7 days after onset.⁴⁰ Viral infection frequently is cleared by the time lumbar punctures are performed; therefore CSF should be tested both for IgM and by PCR to maximize the chances of making a specific diagnosis.

Virus can be recovered from brain biopsy and autopsy material in special reference laboratories, by intracerebral inoculation of baby mice and cell cultures.

DIFFERENTIAL DIAGNOSIS

Other mosquito-borne arboviruses also cause encephalitis—West Nile, Banna, and Chandipura viruses—and may be responsible for occasional or epidemic encephalitis in the same regions where JE occurs.³² Because specific diagnostic assays are even less accessible for these infections than for JE virus itself, they may be responsible for some of the cases currently attributed to JE. Infections caused by West Nile virus, and also dengue virus, which frequently produces encephalopathy, are particularly difficult to differentiate by routine serologic methods because of the antigenic relatedness of the viruses.⁶⁶ JE often cannot be differentiated clinically from other causes of viral encephalitis and has also been misdiagnosed as tubercular or pyogenic meningitis.^{56,77} Enterovirus 71, Nipah virus, and hepatitis E virus—the latter two also associated with pig contact—are transmitted in Asia and can present with CNS signs and symptoms. Other infections that may enter the differential diagnosis include typhoid fever, which can present with tremor and lethargy similar to the prodrome of JE. Acute encephalitis with seizures is encountered in two-thirds of patients with neurocysticercosis, a prevalent chronic condition in some areas of Asia that may increase the risk for acquiring JE (see [Pathophysiology](#)). Where poliomyelitis still has not been confirmed to be eradicated, JE should be included among the possible causes of acute flaccid paralysis.

Noninfectious causes of acute encephalopathy can be considered, as well, including heat stroke, autoimmune encephalitis, vascular occlusion and intracranial hemorrhage, acute electrolyte disturbances, Reye syndrome, lead encephalopathy and other poisonings (including insect repellent toxicity), and inherited metabolic disorders.¹⁰²

TREATMENT

No specific antiviral therapy is available. Supportive care and control of increased intracranial pressure are critical for a good outcome. Mannitol or hypertonic saline is used routinely to control raised

intracranial pressure, and early high-dose dexamethasone therapy was shown to have no clinical efficacy in a prospective controlled clinical trial.⁴¹ Other supportive measures, including control of fever and seizures, attention to fluid balance, respiratory support, and prevention and treatment of secondary infections, have contributed to increased survival and improved outcomes. A small randomized double-blind placebo controlled trial of intravenous immunoglobulin in children with JE demonstrated higher levels of neutralizing antibodies in the treatment group, but no difference in outcome measures.⁹¹ A few patients have been treated with interferon- α , but its efficacy has not been evaluated in wider trials.³⁶ Small interfering and hairpin RNA molecules, and minocycline, administered as an immunomodulator, are being investigated as therapeutic agents.

PROGNOSIS

The case-fatality ratio varies from 5% to 35%, depending on the accessibility and quality of supportive care.¹¹ Younger children (<10 years) are more likely to die of the infection and to have more serious neurologic complications acutely and as sequelae. Gross neurologic impairment, such as paralysis, weakness, abnormal muscle tone, seizures, ataxia, and extrapyramidal movement disorders, are found in approximately one-third to one-half of recovered patients several months to a year after onset.^{38,65,72,96} Electroencephalographic abnormalities have been detected in more than 50% of surviving children 1 year after recovery. The graver clinical consequences of JE, in contrast to other forms of encephalitis necessitating hospitalization, were clearly shown in a follow-up study 6 to 27 years after hospitalization that disclosed neurologic deficits on examination in 22% versus 2% of the subjects and subnormal intelligent quotients in 28% versus 2%, respectively.²⁵ Thus, in areas where the disease is prevalent, JE may account for substantial disability in the resident population. Optic atrophy and chronic seizures have been reported to have a delayed onset of 3 to 17 years after hospital discharge, indicating the need for long-term follow-up.^{25,95}

PREVENTION

JE vaccine is administered routinely under the World Health Organization Expanded Programme on Immunization and national schedules in most Asian countries (see Fig. 176E.3). Vaccination effectively reduces the incidence of JE disease.^{108,116} Several JE vaccines are used in humans: (1) mouse brain–derived killed, inactivated; (2) cell culture–derived live, attenuated; (3) Vero cell–derived killed, inactivated; and (4) genetically engineered live, attenuated chimeric vaccine.^{33,108,112} Availability of these products varies by country. Only the Vero cell–derived vaccine is licensed in the United States.

The first JE vaccine was the mouse brain–derived inactivated vaccine (JE-VAX) and was the only vaccine available for decades. Although highly immunogenic, JE-VAX had a considerable incidence of adverse side effects, including rare allergic and neurologic effects.^{83,84} Its use has been replaced with the cell-derived vaccines, and worldwide production of JE-VAX was halted in 2006.

The cell-derived live, attenuated vaccine made from the SA14-14-2 strain was first licensed in China in 1988 and is now the most widely used vaccine in JE-endemic areas, also licensed in India, South Korea, Nepal, Sri Lanka, Cambodia, Laos, Myanmar, and Thailand. The SA14-14-2 vaccine is highly immunogenic, achieving high levels of neutralizing antibodies after one dose in 80% to 99% of children, and almost complete protection after two doses.^{18,54,76} Previously given at 1, 2, and 6 years of age, the 2015 WHO position statement for JE vaccine recommends a single dose at 8 months or older.¹⁰⁷ Although the strain is highly attenuated, with low reactogenicity, safety studies are limited. A report of four JE cases occurring in temporal relationship to vaccination could not distinguish vaccine failure from vaccine-associated encephalitis, indicating a need for additional safety surveillance.⁴⁷ No data are available on its use in HIV-infected or other immunocompromised patients.

The inactivated Vero cell–derived JE vaccine, also made from the SA14-14-2 strain, is licensed in the United States for children older than 2 months and adults, and internationally for use in travelers.^{12,13,45,112} Two intramuscular doses separated by 28 days produces seroconversion

to protective neutralizing antibody titers in 96% of adult subjects with few local and systemic reactions.⁴⁹ After primary immunization, seroprotection rates were 83%, 58%, and 48% at month 6, month 12, and month 24, respectively.²⁶ When subjects were vaccinated 15 months after primary immunization, all responded to the booster dose with persistence of a high geometric mean titer (GMT) at 1 year later.¹³ Trials in children indicate 100% seroconversion after two 3- μ g (children <3 years) or 6- μ g doses (children 3–18 years), with protection in 88% of children 2 years and younger and 95% of children 3 years and older at 6 months after the two-dose series.¹⁴ Reactogenicity was similar to that of the PCV7 control vaccine, and no safety signals have emerged in postmarketing surveillance.⁹⁸

The live chimeric vaccine leads to seroconversion in 97% of adults 6 months after a single dose, with 93% retaining protective antibody levels at 5 years.¹⁰³ Antibody persistence was modeled to show that 90% of subjects would remain seroprotected at 8 years.^{22,24} Well-tolerated, compatible, or sequential administration with yellow fever 17D vaccine was shown.⁷³ In 12- to 19-month-old toddlers, more than 92% seroconverted, with persistence of antibodies in more than 84% after 2 years.^{19,30} Cautions associated with the use of the live vaccine in immunocompromised persons, at the extremes of age, and in other populations have not been specifically defined.

The WHO recommends the following dosing schedule for JEV in endemic areas:

- Inactivated Vero cell–derived vaccine: primary series according to manufacturer's recommendations (these vary by product), generally two doses at 4-week intervals starting the primary series at 6 months and older in endemic settings.
- Live, attenuated vaccine: single dose administered at 8 months and older.
- Live, recombinant vaccine: single dose administered at 9 months and older.¹⁰⁷

The duration of protection of these vaccines is not known, although protection of childhood vaccination extends into adulthood and likely confers long-lasting immunity. A surveillance of birth cohorts in Taiwan, where a vaccination program has been in place for more than 40 years using mostly the inactivated mouse brain–derived vaccine, demonstrated neutralizing antibodies in 54% of people whose last JE virus vaccine was more than 20 years earlier.⁴² Antibodies did appear to wane in older individuals. Long-term follow-up of subjects receiving the inactivated Vero cell–derived SA14-14-2 vaccine showed persistence of protective levels of antibodies in 96%, and modeling predicted duration of approximately 14 years.⁸¹

More than 100 JE cases have been reported in travelers; therefore, vaccination of certain travelers is recommended.⁶ Current US recommendations specify vaccination for expatriates, for travelers spending 30 days or more in an endemic area during the transmission season, and for persons with briefer itineraries if they have a high risk for exposure (see Table 176E.1).^{12,37} The course of immunization should be completed 7 to 10 days before the onset of travel. These recommendations are highly conservative, however, because cases in travelers have been reported in individuals with briefer itineraries and without the cited risk factors, who later died or survived with serious neurologic damage. The narrow criteria defined in the recommendation are a legacy of committee efforts to limit use of the highly reactogenic mouse brain–derived vaccine, which was the only licensed vaccine when recommendations initially were formulated.¹² With the availability of a safer inactivated vaccine, the changed risk-to-benefit ratio of vaccination has prompted reconsideration of these recommendations.^{6,7,68,108} Because the illness has such a high clinical impact and the risk for acquiring the infection is serendipitous—although low—thoughtful counseling is needed while discussing the risks for the disease, vaccine cost, and other factors so that travelers can make an informed decision (see Table 176E.1). From a public health perspective, routine childhood vaccination with the live SA14-14-2 vaccine has been shown to be highly cost effective.^{62,110} Pig vaccination is ineffective and impractical, although keeping pigs sties and pig production facilities at a distance from the human population can reduce disease risk.

Another avenue for JE prevention could be vector control. Mosquito control is impractical in most areas where JE is endemic, but agricultural

practices, such as schedules of rice production and changes in water levels, and nontargeted effects of agricultural pesticides have had secondary effects in reducing the vector population and cannot be excluded to have reduced human infections. A growing area of study is the use of the bacterial endosymbiont *Wolbachia* to reduce viral proliferation, a strategy that has shown reduced replication of yellow fever, West Nile, and Chikungunya viruses and potentially JE.⁴⁶

Although vaccination is recommended to prevent infection and illness, avoidance of outdoor activities during the evening hours, staying in screened or air-conditioned quarters, and sleeping under a bed net also will lower the risk for acquiring the illness by reducing exposures to vector mosquitoes. Wearing long-sleeved shirts and long pants and using mosquito repellents on clothing and exposed skin are recommended for outdoor activities.

176F ■ Murray Valley Encephalitis

Roy A. Hall • John Aaskov

Outbreaks of an acute, severe, encephalitic illness, clinically similar to Japanese and St. Louis encephalitis, occurred in rural areas of southeastern Australia in 1917, 1918, 1922, 1925, 1951, and 1974.^{1,10,15-17} and in north and northwestern Australia in 1981, 1993, 2000, and 2011.^{9,13,44,45} Approximately 437 cases were reported in these 10 outbreaks.⁴⁴ They are thought to represent a single entity for which various names (Australian X disease, Murray Valley encephalitis, Australian encephalitis) have been used.

Case-fatality rates, as high as 70% in the early years,^{10,12} declined to 20% in the 1974 outbreak and have remained at about this level since then.^{4-6,11,13} However, significant residual neurologic disability occurs in as many as 50% of survivors.^{11,13}

The presence of this disease in Papua New Guinea was confirmed in 1956.²¹ The causative virus was transmitted to experimental animals as early as 1918,^{7,12} although those strains could not be maintained. The definitive isolation and characterization of Murray Valley encephalitis virus in 1951²⁰ led to epidemiologic studies that suggested its survival in bird-mosquito cycles in northern Australia but not in the area of epidemic occurrence in southern Australia.¹

Murray Valley encephalitis is caused by Murray Valley encephalitis virus. In an effort to dissociate a disease from a specific locality, the term *Australian encephalitis* was proposed by residents of the Murray Valley region for the disease caused by Murray Valley encephalitis virus. Some researchers subsequently have attempted to expand the term *Australian encephalitis* to include encephalitis caused by any Australian arbovirus. Because the term *Australian encephalitis* has no scientific validity and is ambiguous, it should not be used.

ETIOLOGIC AGENT

Murray Valley encephalitis virus was isolated postmortem from the brain of patients in 1951 and 1974 and shown to be a flavivirus, related antigenically to Japanese encephalitis virus.^{20,29}

A partial nucleotide sequence of Murray Valley encephalitis virus¹⁴ confirmed the previous classification of this virus, on serologic grounds, as being a member of the Japanese encephalitis, St. Louis encephalitis, West Nile fever subgroup of flaviviruses.³⁹ Four genotypes of Murray Valley encephalitis have been identified, two exclusively from Papua New Guinea.^{25,30} However, more recent isolates from Papua New Guinea cluster with Australian strains in genotype 1.⁵⁰

TRANSMISSION AND EPIDEMIOLOGY

The mosquito *Culex annulirostris* is thought to be the major vector of Murray Valley encephalitis virus,^{17,18,33} although other mosquitoes, such as *Aedes normanensis*, *Aedes tremulus*, and *Culex quinquefasciatus*, also may play a significant role in transmission of the virus.⁸

Murray Valley encephalitis virus is thought to survive in cycles of infection between birds and mosquitoes in northern Australia and Papua New Guinea,¹ where regular infection of humans and other animals is indicated by seroconversion in the summer-autumn “wet” season,¹⁷ as well as by clinical disease.^{8,44} Studies also suggest that the virus might survive, after vertical transmission, in desiccation-resistant eggs of *A. tremulus* mosquitoes.⁸ Epidemics that occurred in more populous areas of southeastern Australia are thought to have followed the introduction

of virus when abnormal spring rainfall allowed chains of bird-mosquito transmission to occur through northern Australia.² However, several studies have also suggested that interepidemic survival of virus occurs in southern Australia.²²

Although disease occurs most commonly in children, clinical infection occurs in individuals of all ages (see [Clinical Manifestations](#)). Data are insufficient to determine whether the lower incidence of disease in adults is due to immunity acquired from previous subclinical infections.

Recent reports of sporadic clinical Murray Valley encephalitis virus infection in horses, with pathologic changes in the brain and spinal cord similar to those seen in humans,^{5,24} confirm a previous, unconfirmed report of possible Murray Valley encephalitis virus infections in horses²³ and raise the possibility that both wild and domestic horses could play a role in the transmission and dissemination of this virus. The association of Murray Valley encephalitis virus infection with neurologic disease in horses also was observed in a large outbreak of equine encephalitis in southeastern Australia in 2011. Although a virulent strain of the Kunjin subtype of West Nile virus was responsible for most cases, Murray Valley encephalitis virus RNA was detected in the brain of several diseased animals.⁴³

CLINICAL MANIFESTATIONS

An initial period of nonspecific, fluctuating, prodromal symptoms and signs, with fever, headache, nausea, vomiting, muscle pain, and photophobia, is followed within 2 to 5 days by drowsiness, mental obtundation, confusion, disorientation, incongruous behavior, ataxia, speech disturbance, or seizures.³² Bennett⁶ recognized three groups of patients according to eventual clinical outcome:

1. Patients with mild disease commonly had disturbed mentation short of coma, incoherent or slurred speech, aphasia, speech perseveration, incontinence, neck stiffness, intention tremor, and limb hypertonicity but rarely required assisted ventilation. The neurologic changes stabilized in 5 to 10 days, and the patients' clinical condition improved.
2. Patients with severe disease showed more profound central nervous system (CNS) involvement consisting of impairment of consciousness to coma, more marked signs of upper motor neuron involvement, and pharyngeal or respiratory paralysis requiring assisted ventilation.
3. In fatal cases, patients had either spastic quadriplegia progressing to almost complete loss of nervous function or severe disease with superimposed infection.

There also may be a fourth group with even milder signs and symptoms than Bennett's group 1. These are patients with mild or no encephalitis whose principal features are fever and headache.⁴²

PATHOLOGY

A period of viremia probably precedes infection of the CNS, during the 1- to 3-week incubation period,¹ but it has not been demonstrated. Pathologic changes in fatal cases were restricted to the CNS and included extensive perivascular cuffing (especially in the cortex), lymphocytic infiltration of the meninges, neuron degeneration and neuronophagia in the cerebellum and spinal cord, and thalamic necrosis. Evidence of repair, including calcification, was described in patients who died late in the course of the disease.^{7,11,12,38,41} These pathologic changes do not distinguish Murray Valley encephalitis from other arthropod-borne encephalitides.

In rodents infected peripherally with Murray Valley encephalitis virus, the virus enters the CNS through the olfactory pathway after replicating in regional lymph nodes. From the olfactory lobe, it spreads through interconnected neural circuits to the cortex, hippocampus, thalamus, cerebellum, medulla oblongata, and spinal cord. Extensive neuronal necrosis was observed in the olfactory bulb and hippocampus. The severity of the subsequent encephalitis correlated with the magnitude of mononuclear and polymorphonuclear cell infiltrates. Infiltration of neutrophils was preceded by increased expression of tumor necrosis factor- α and the chemokine N51/KC in the CNS. Previous depletion of neutrophils or inhibition of inducible nitric oxide synthetase resulted in prolonged survival and decreased incidence of mortality in mice infected with Murray Valley encephalitis virus.^{3,34} However, the

pronounced mononuclear cell content of cerebrospinal fluid in some patients with Murray Valley encephalitis^{11,21} contrasts with the picture in rodents.³⁴ However, a recent study of the pathogenesis of Murray Valley encephalitis virus in weanling New Zealand white rabbits suggests this animal model more closely mimics human infection with this virus. Rabbits infected through the footpad developed low-titer viremias with dissemination of virus to the lymph nodes and spleen. As with humans, most infections in the rabbits were asymptomatic and were associated with no, or mild, pathology in the CNS.⁴⁸

DIAGNOSIS

Clinical and epidemiologic features may suggest the diagnosis of Murray Valley encephalitis, especially during recognized epidemics, but individual cases may be difficult to distinguish from cases of encephalitis or encephalopathy of other cause (e.g., herpesvirus or Japanese encephalitis or Kunjin viruses).^{6,36,51} A differential diagnosis of Murray Valley encephalitis may be assisted by observing signs attributable to spinal cord involvement and cranial nerve palsies, tremor, and frequency of seizures (seizures rarely develop in adults with Murray Valley encephalitis, whereas they may occur in up to 90% of children). Although computed tomographic scans in these patients may be normal and electroencephalograms may not show focal features,¹¹ magnetic resonance imaging (MRI) reveals changes within a week of symptoms, similar to those reported in the brain of patients with Japanese encephalitis²⁶—thalamic edema, hypointensity on T1-weighted images, and hyperintensity on T2-weighted images.^{19,27,28} Changes also were noted in the reticular formation, the substantia nigra, and the cervical spinal cord.¹⁹ In the absence of serology, MRI findings might be regarded as diagnostic of an infection with herpes simplex virus rather than with Murray Valley encephalitis virus.⁵¹

Establishment of a specific diagnosis depends on serologic evidence of infection concurrent with disease. Detection of IgM antibody that reacts with Murray Valley encephalitis virus in enzyme-linked immunosorbent assays is the most useful indication of recent infection. Other flaviviruses, especially Kunjin virus, may cause encephalitis, subclinical infection, or minor illness during epidemics of Murray Valley encephalitis,⁴⁴ and interpretation of serologic cross-reactions between Kunjin and Murray Valley encephalitis viruses may require specific tests (e.g., neutralization) with several viruses.¹⁷ Serologic tests for the laboratory diagnosis of Murray Valley encephalitis are not available commercially and so are performed only at larger regional laboratories. Isolation of virus has not been successful for antemortem diagnosis. Reports^{19,35} document the detection of Murray Valley encephalitis viral RNA in serum or cerebrospinal fluid from patients by use of reverse transcriptase polymerase chain reaction (RT-PCR), and some laboratories use in-house RT-PCR assays as part of routine diagnosis.^{35,40}

TREATMENT AND PROGNOSIS

No specific antiviral therapy is available. Administration of corticosteroids has been recommended during the acute phase of the illness to reduce brain edema. Artificial respiration has been lifesaving, and all patients should be transported to base hospitals with facilities for the management of patients with respiratory paralysis.⁶ Most patients also require parenteral nutrition or nasogastric feeding.¹¹

The early epidemics left some patients with neurologic and psychiatric sequelae, but the lower case-fatality rate in recent outbreaks, presumably because of use of modern intensive care techniques, has been associated with a high rate of residual disability.^{11,13} Bennett⁶ observed 18 patients up to 16 months after they experienced infection. Four of 11 patients with mild disease had emotional problems and mild degrees of impaired motor coordination and mental acuity. All 7 patients with severe disease had serious defects, including paraplegia or quadriplegia and mental disturbance. This pattern of high residual disability has continued to the present.^{11,13,47}

PREVENTION

Because of the irregularity of outbreaks and the large areas over which they occur, implementation of cost-effective measures to prevent Murray

Valley encephalitis is difficult. There is no evidence that mosquito control measures, even during outbreaks, have had any effect on transmission of Murray Valley encephalitis virus. Several Australian states have established surveillance programs for Murray Valley encephalitis virus employing flocks of sentinel chickens to provide warning of transmission of this virus. In combination with observing rainfall patterns, this information appears to have predictive value and serves to alert public health authorities and local residents to the need of enhanced mosquito management and avoidance measures.⁴⁶

A more recent technology to detect Murray valley encephalitis virus RNA in mosquito saliva expectorated during feeding on sugar-baited, nucleic acid preservation cards has the potential for use in surveillance programs over much wider areas than the sentinel chicken flocks but has yet to be evaluated as an early warning tool.⁴⁹

There is no vaccine to prevent infection with Murray Valley encephalitis virus; however, studies in animal models have shown that cross protective immunity can be generated against the virus with an inactivated Japanese encephalitis vaccine in the presence of a suitable adjuvant.³¹ Although these data suggest that the recently licensed Japanese encephalitis virus vaccine (IMOJEV)³⁷ might protect against infection with Murray Valley encephalitis, the cost of the human clinical trials to confirm this renders the use of the vaccine for this purpose unlikely.

176G ■ Tick-Borne Encephalitis

Gail J. Harrison • Andrea Duppenhaler • Christoph Aebi • Theodore F. Tsai

Tick-borne encephalitis (TBE) refers to the neurotropic hard tick-transmitted flaviviral infection caused by tick-borne encephalitis virus (TBEV), which occurs across the Eurasian landmass from the Far East to western Europe. TBE is usually divided into European, Far Eastern, and Siberian subtypes, and it infects thousands of people each year in these regions. It has been a growing public health problem in Europe and other parts of the world since 1999.⁸⁷ The Far Eastern form of the disease frequently is called *Russian spring-summer encephalitis* (RSSE); in Europe, where the disease is distinctly milder and often biphasic, it is called *tick-borne encephalitis*, *spring-summer meningoencephalitis*, *central European encephalitis*, or, because sometimes it is transmitted by raw infected milk, *biphasic milk fever*.^{31,43,82,124} The presence of TBEV in ticks and the Roe deer, in the Netherlands, has recently been reported.⁶¹

HISTORY

After an outbreak of encephalitis in the Far Eastern region of Russia in 1932, Zilber isolated the virus from viremic humans and from *Ixodes persulcatus* ticks.¹⁶⁷ A milder form of the disease with a similar seasonality was described previously in Sweden and Austria, but its etiology was not defined until 1948, when the virus was isolated in the Czech Republic and Slovakia. Milk-borne transmission of TBEV from infected livestock first was recognized in an outbreak in 1951 and 1952.

ETIOLOGIC AGENT

TBEV and the closely related viruses of RSSE and Powassan encephalitis are flaviviruses placed antigenically within a complex of tick-borne flaviviruses that also includes the agents of Kyasanur Forest disease, Omsk hemorrhagic fever, and an encephalomyelitis syndrome in sheep variously called *louping ill* in the British Isles and *Spanish, Greek, or Turkish sheep encephalomyelitis* in their respective countries.⁵¹ Molecular taxonomic studies based on nucleotide sequence differences in the E glycoprotein gene of the virus show the early divergence of a mammal-associated clade from seabird-associated agents. Viruses in the mammal-associated clade exhibit a continuous east-to-west cline consistent with an evolutionary origin of TBEV in the Far East and dispersion westward to Europe and the British Isles (Fig. 176G.1).^{39,103}

ECOLOGY

The viruses of RSSE and TBE are transmitted principally by hard ticks in the *Ixodes ricinus* complex—*I. ricinus* in Europe and *I. persulcatus* in the Far East.^{43,82,124} Other tick vectors include *Ixodes arboricola*, *Ixodes hexagonus*, *Haemaphysalis punctata*, *Haemaphysalis concinna*, *Dermacentor marginatus*, and *Dermacentor reticulatus*. Viral circulation is maintained by continuous horizontal infection between ticks and animals and through the winter by vertical transmission in vector ticks and by latent infection in hibernating animals. The viruses are transmitted transstadially from larval to nymphal to adult tick stages and also transovarially. All stages of the tick and both male and female ticks transmit infection to animals and humans. Ixodid ticks feed on three hosts, one for each of the stages, during the typical 3-year life cycle. Larval and nymphal ticks feed preferentially on birds and small mammals, such as wild mice, voles, and dormice; adult ticks feed on larger mammals, such as roe deer, hedgehogs, foxes, hares, badgers, deer, domestic livestock (pigs, goats, sheep, and cows), dogs, cats, and humans. RNA sequence heterogeneity of the 5' noncoding region in different TBEV isolates recovered from the same biotope suggest that virus populations consist of subtypes with specificities for individual vertebrate hosts.¹⁵ Infections in animals, except occasionally in dogs, are asymptomatic, and the viremia is of brief duration. Therefore a large population of susceptible vertebrate hosts is needed to maintain viral transmission. Human infections are incidental to the natural cycle of transmission. Birds and large mammals contribute to the spread of vector ticks and viral foci.⁹⁴

Ticks in the *I. ricinus* complex require high soil and ambient humidity (>80–90% relative humidity) and moderate temperature, within the 8°C (46.4°F) isotherm. They typically are found in the transitional vegetation zone from the forest edge to fields or meadows or in areas where dense brush or ground vegetation provides a sheltered micro-environment. Vector ticks are absent from mountainous areas with an elevation above 1200 to 1500 m. Foci of TBE transmission are restricted geographically and ecologically to these biotopes and have tended to be highly stable over years. However, global warming has been speculated to underlie the changes, both expansion and contraction of transmission foci, in northern and central-southern Europe, respectively.^{93,124} New data also suggest a shift of tick activity to higher altitudes in recent years, potentially allowing vertical expansions of TBE foci.²⁶

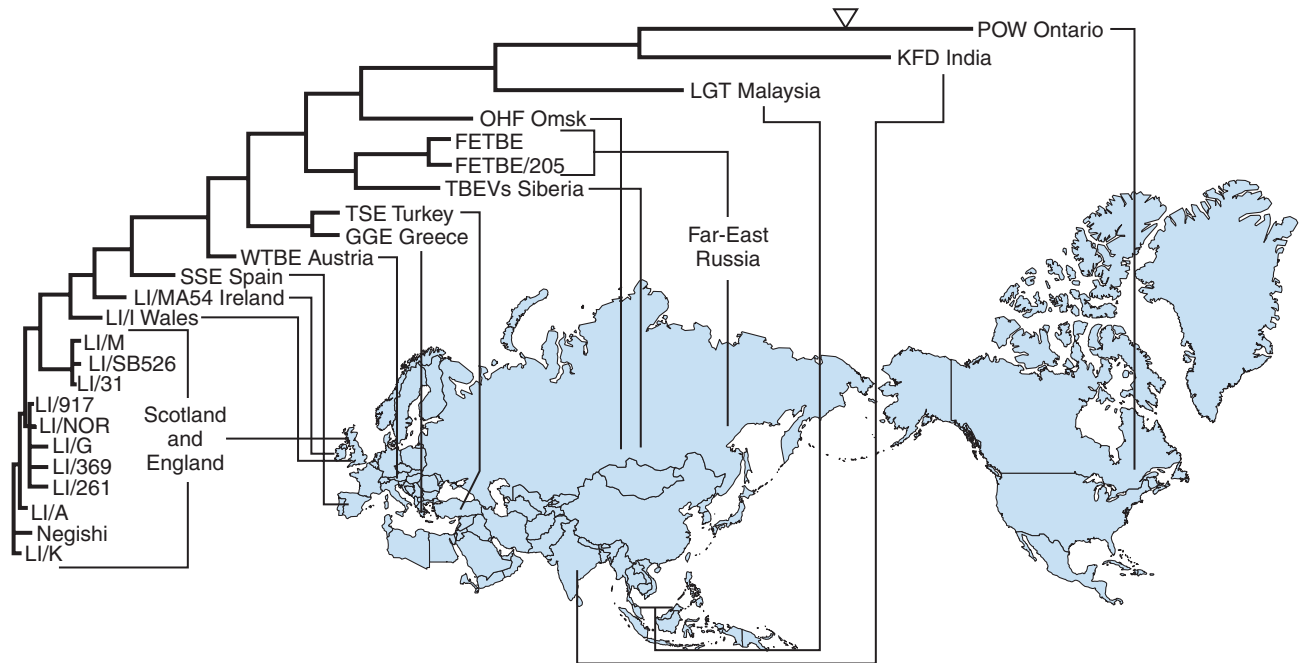

FIGURE 176G.1 Cladogram of tick-borne encephalitis complex viruses based on E gene sequences presented from west to east with respect to louping ill (LI) virus. FETBE, Far Eastern tick-borne encephalitis; GGE, Greek goat encephalitis; KFD, Kyasanur Forest disease; LGT, Langat; OHF, Omsk hemorrhagic fever; POW, Powassan encephalitis; SSE, Spanish sheep encephalitis; TSE, Turkish sheep encephalitis; WTBE, Western tick-borne encephalitis. The phylogenetics of these and other mosquito-borne flaviviruses are rooted in the Powassan branch indicated by the triangle. (From Zanotto PM, Gao GF, Gritsun T, et al. An arbovirus cline across the Northern Hemisphere. *Virology*. 1995;210:152-159.)

Tick activity varies with seasonal temperature and humidity. In central Europe, activity begins in March and April, reaches a peak in May, and declines during the summer in July and August. With the return of cooler temperatures, a second peak of activity occurs in September. In temperate regions, tick activity begins later and is greatest in the summer months. In Mediterranean climates, ticks are most active from November to January.

In foci with hyperendemic transmission, tick density may exceed 1/mm². Viral infection rates in ticks generally are in the range of 0.1% to 5%.¹⁸ These rates typically are 10-fold lower than *Borrelia burgdorferi* (sensu lato) infection rates in *I. ricinus* in the same areas, although *I. persulcatus* infection rates greater than 10% have been reported.⁷⁵ The mechanisms underlying this difference are unclear but may include the following¹¹⁵:

- The variable infectiousness of the agents and their interactions with modulatory factors in tick saliva
- The relatively brief duration of TBE viremia in animals, which lasts only a few days and thus results in a reduced chance of transmission of virus to feeding ticks, as opposed to the persistent *B. burgdorferi* infections in rodents, with tick feeding more likely to result in infection
- The potential differences in the principal reservoir hosts for the respective infectious agents, with a more limited and focal distribution of important hosts for TBEV, such as goats.

The two agents evidently do not interfere with each other in their infection of *I. persulcatus* ticks; dually infected ticks and singly TBEV-infected and *Borrelia*-infected ticks stand in a ratio of approximately 1:4:14.⁷⁵ *I. ricinus* also can be infected with and transmit *Francisella tularensis* and *Anaplasma phagocytophilum*, the agent of human granulocytic ehrlichiosis.¹⁵⁹

The geographic distributions of RSSE and European TBE correspond to the ranges of their principal tick vectors; however, transmission is highly focal within this range because of the locations of biotopes that support viral circulation (Fig. 176G.2). New foci are reported periodically as a result of better recognition of the disease, its natural spread, human

modifications of the landscape, and environmental and climate changes (e.g., global warming).^{36,65,93,124}

EPIDEMIOLOGY

TBE is transmitted through hard tick bites or through ingestion of unpasteurized dairy products. TBE has been recognized in all countries of Europe except Portugal and the Benelux countries, but endemic transmission is most intense in central Europe.^{82,124} Slovenia currently has one of the highest notified incidences of TBE in Europe.³⁵ TBE also has been detected in Japan and northern mainland China, in areas of forests, presence of *I. persulcatus* ticks, and appropriate altitude and climate.¹⁴⁹ Human TBE has increased since the 1990s in all endemic European countries except Austria, where a well-organized vaccination campaign was initiated.^{6,62,93} The incidence of TBE previously ranged as high as 50 per 100,000 population in Austria, Poland, Hungary, Russia, Czech Republic, Slovakia, Bulgaria, and former Yugoslavia; in certain areas, similar levels of transmission still may prevail. TBEV also has been reported recently in the Netherlands in 2% of the ticks and Roe deer population of the areas, and there is increasing evidence of TBEV transmission in the Netherlands.^{20,53,61,158}

Vaccination has reduced the incidence of disease regionally, especially in Austria, where a national program of immunization since 1981 has reduced the incidence to less than 1 per 100,000 population.¹⁶⁵ However, breakthrough illnesses, and rarely even fatal breakthrough cases of TBE, have been reported in vaccinated children and adults and in elderly individuals.^{14,145} Currently, isolated cases are reported from Norway, Denmark,¹⁴⁶ France,⁴⁷ Greece, and Liechtenstein, and fewer than 200 cases are reported annually in Sweden, Germany, and Italy. The Swedish Institute for Communicable Disease Control recently reported the highest annual incidence of human TBE in 2011 and 2012.⁶² Switzerland reported a threefold increase in human TBE cases between 2004 and 2006,¹⁶⁶ which resulted both from more infections in endemic areas and from infections in newly recognized foci. Since then, the number of newly diagnosed cases in Switzerland has decreased again but has remained

FIGURE 176G.2 The geographic distributions of Russian spring-summer encephalitis and European tick-borne encephalitis correspond to the ranges of their principal tick vectors; however, transmission is highly focal within this range because of the locations of biotopes that support viral circulation.

higher than before 2004. In the Far East, cases of RSSE occur principally in forest workers. The disease is recognized in Russia and China, and the first cases acquired in Japan (transmitted by *Ixodes ovatus*) were reported recently.

Within each country, the distribution of cases is highly focal in certain areas and may vary with each year. Local seroprevalence may exceed 20%, but the general seroprevalence usually is less than one per 100,000 population. Frequent exposure during long-term residence leads to a general trend of increasing seroprevalence with age. Seroprevalence rates as high as 50% have been observed in groups at high risk for exposure, such as farmers and forestry workers. Although, in general, rates are lower (1–5%) and in certain groups are similar to the seroprevalence of hantaviruses, lymphocytic choriomeningitis virus, and *Anaplasma* spp., *B. burgdorferi* seroprevalence rates are 10-fold higher or more.^{107,113} The frequency of clinical cases of TBE, borreliosis, and dual infection closely approximates the relative frequency of tick infection, singly and dually. Adults 20 to 50 years of age characteristically accounted for most of the cases. In some studies, cases in males (adults and children) predominate by a ratio of 2:1.^{32,48,92}

Cases have occurred in children as young as 3 weeks,^{59,66} but generally, risk in children increases with age as a result of their increased mobility and activity in the sylvatic environment.⁹² These epidemiologic patterns are changing in areas with high immunization coverage.¹⁶⁵ Vaccination effort has focused principally on hyperendemic areas and on high-risk occupational groups such as forestry workers. The low number of cases currently reported from areas where vaccination coverage is high belies the continued transmission of virus in these locations.

Cases may be acquired during outdoor activities, such as berry picking and mushroom gathering, and infection occasionally has been acquired from ticks brought from endemic areas on Christmas trees and other objects. One study found that the seroprevalence in Swedish orienteers (1%) was not substantially different from the general seroprevalence in residents of Stockholm County (5%), an area where TBE is endemic. The absence of a higher risk for acquiring TBE in persons with occasional sylvatic exposure reflects the low infection rate of ticks and the generally low risk to persons with sporadic or short-term exposure. Neither of two studies of American soldiers stationed in central Europe found a clinical case, although one seroconversion in 3297 person-months of exposure, an infection rate of 0.9 per 1000 person-months and four seroconversions in 959 persons (0.4%) were detected.^{105,134} With the dissolution of the former Soviet Union and increasing commerce with eastern Europe, interest in the risk for TBE being acquired by travelers to Europe and Russia has increased. The available data suggest that the risk is low for most travelers and that vaccination is not indicated except for unusual circumstances of prolonged stay in an endemic area.

The seasonal distribution of cases lags roughly 1 month behind that of tick activity and extends from April until November. The peak incidence in Sweden is in August; in Austria, the peak occurs in June and July, with a secondary rise in October.

Milk-borne TBE previously accounted for 10% to 20% of all cases in central Europe. Infections frequently were acquired from consuming unpasteurized milk or cheese from infected goats, sheep, and cows, and outbreaks resulting in thousands of cases have been reported. Transmission from infected milk now is a rare occurrence, but as recently as 1994, an outbreak in Slovakia led to 7 cases in a group that regularly drank raw milk from a family goat.⁷⁵ Also, an outbreak of 21 human cases caused by contaminated cheese produced from unpasteurized sheep milk has been reported.¹⁶² Contact infection, acquired during slaughter of an infected goat, also has been observed.

Recently, transmission of TBE to three patients who received solid organ transplants from a single donor occurred. They developed fatal encephalitis within 17 to 49 days after transplantation, and the illness was confirmed to be TBE by RT-PCR of brain tissue and cerebrospinal fluid. The high fatality rate in these patients was most likely related to their immunosuppression. These cases raise the awareness that organ donors from TBE endemic areas should be screened for TBEV infection.¹⁵⁹

CLINICAL MANIFESTATIONS

Seroepidemiologic studies indicate that as many as 90% of human infections with TBEV remain asymptomatic or result in a nonspecific illness.^{2,7,46,70} The classic manifestation of the European form of TBE is an acute febrile illness characterized by a biphasic course consisting of a nonspecific prodromal syndrome followed by central nervous system (CNS) disease (Fig. 176G.3).^{42,156} Infection with TBEV may occur solely as the primary, nonspecific phase without the secondary CNS phase.^{31,98} Infection with Far Eastern strains of TBEV results in a more severe, monophasic illness that progresses directly to neurologic involvement with a poorer prognosis for survival and full recovery. TBE has been observed in all age groups. The median age in pediatric case series is 8 to 10 years (range, 0–17 years).^{22,48,92,96,153} The youngest patient with serologically and virologically documented TBE described in the literature was a 17-day-old infant.⁶⁶ Congenital infection has not been reported. Fatal TBE disease has been described in immunocompetent individuals and immune-compromised transplant recipients.¹⁵⁹

The clinical features of TBE in children are summarized in Table 176G.1. The clinical spectrum ranges from nonfocal mild aseptic meningitis to severe meningoencephalitis, without paralysis, or meningoencephaloradiculitis, associated with paralysis. Patients may also have a cranial nerve palsy or cerebellar signs of ataxia on presentation, as well as aphasia and autonomic dysfunction.^{13,158} A rare abortive form of TBE may also occur, as well as a chronic progressive form of TBE. There is also a postencephalitis syndrome. The diagnosis of TBE should be considered in all acutely ill patients with fever, CNS abnormalities, and a history of potential tick exposure or ingestion of raw milk in an area endemic for TBE, especially if the patient presents during peak

FIGURE 176G.3 Clinical course of tick-borne encephalitis (TBE) in a 5-year-old boy exposed to a tick bite in a known endemic area for TBE in the pre-alpine region of central Switzerland. Lumbar puncture on admission revealed mild cerebrospinal fluid (CSF) pleocytosis ($14 \times 10^6/L$, 50% polymorphonuclear cells). Serum anti-TBE virus immunoglobulin (Ig) M and IgG were present; serum and CSF antibodies against *Borrelia burgdorferi* were absent. CSF enteroviral polymerase chain reaction was negative. Recovery was uneventful.

TABLE 176G.1 Clinical Features of Serologically Documented Tick-Borne Encephalitis in Five Pediatric Case Series (333 Children)

Clinical Features	Rate (%)
History	
Tick exposure	47–78
Biphasic illness	77–90
Major Symptoms at Presentation	
Fever $>38.0^\circ\text{C}$ (100.4°F)	100
Headache	90–100
Vomiting	60–90
Central Nervous System Signs	
Nuchal rigidity	74–90
Photophobia	10–25
Impaired consciousness	9–11
Ataxia or tremor	5–26
Seizures	0–5
Paresis	0–5
Extent of Central Nervous System Involvement	
Meningitis alone	49–89
Meningoencephalitis	9–48
Meningoencephalomyelitis	0–5
Fatal outcome	0
Cerebrospinal Fluid Parameters	
Pleocytosis $>15 \times 10^6/L$	98–100
Glucose normal	100
Protein elevated	9–55
Abnormal electroencephalogram	80–87

Data from references 21, 44, 62, 82, 89, 144.

tick season April to November.¹³ A high degree of diagnostic awareness is required because the clinical presentation of TBE is nonspecific. After an incubation period of 2 to 28 days, in most cases 7 to 14 days,^{32,48,92,96,156} the patient may have a prodromal illness consisting of fever, malaise, nausea and vomiting, headache, myalgia, and, occasionally, upper respiratory tract symptoms.^{32,48,77,156} Defervescence occurs after 2 to 7 days, and the patient subsequently remains asymptomatic for 1 to 20 days, usually 2 to 10 days.^{32,48,77,92,153} This prodromal illness may be

absent. In various case series, a biphasic course was reported in 30% to 90% of children with TBE.^{48,68,92,96,153} An abrupt onset of fever, headache, emesis, and symptoms of meningeal irritation heralds the beginning of the second phase of disease.⁹⁶ In adults, no association exists between the length of the incubation period and the severity of clinical illness.⁶⁸ The typical evolution of fever in a child with TBE is shown in Fig. 176G.4.

In this second phase of illness, most affected children (50–90%) have meningitis without clinical evidence of parenchymal CNS involvement.^{48,76,80,96,110,128,153} In adult patients, by contrast, meningitis without encephalitis or myelitis occurs only in 20% to 60% of cases.^{2,68,77,125,144} On physical examination, fever, signs of meningeal irritation, and photophobia are the most common features.^{96,153} In uncomplicated cases, patients defervesce within 5 to 10 days.^{48,92,96,153} Meningoencephalitis, meningoencephalomyelitis, or both manifested by impaired consciousness, seizures, and focal neurologic signs, including limb paresis, associated with meningoencephaloradiculitis, occurs in 0% to 34% of children.^{22,48,70,92,96,153} In a large series of 139 pediatric patients with TBE meningoencephalitis, Lesnicar and coworkers⁹² observed tremor in all patients, impaired consciousness in 27 (7%), ataxia in 18 (5%), behavioral changes in 16 (4%), cranial nerve paresis in 14 (4%), and limb paresis in 11 (3%). In a series of 13 children, Harasek⁴⁸ observed ataxia in 10 patients, somnolence in four, paresthesias and seizures in two each, and central facial palsy and nystagmus in one each. In two of these patients, transient unilateral shoulder girdle weakness that occurred during the second week of CNS disease suggested involvement of the cervical anterior horn or radiculitis. Overall, limb or cranial nerve paresis occurs in 0% to 5% of children with TBE (see Table 176G.1). In a series of 133 children with TBE, Cizman and colleagues²² reported transient paresis in five patients and irreversible hemiparesis in one.

In large case series of predominantly adult patients, a paralytic course secondary to bulbar, spinal, or radicular injury was observed in 5% to 25% of cases.^{70,72,105,144,150,156} Unilateral, flaccid paresis of an upper extremity is the most common manifestation of lower motor neuron disease complicating adult TBE.^{105,150,156} Involvement of the cranial nerves occurs somewhat less frequently and is revealed most commonly by external ocular muscle paralysis (usually cranial nerve VI), peripheral facial palsy (VII), otovestibular manifestations (VIII), or involvement of the pharyngeal muscles (IX, X, and XI).^{32,68,105,147} Lower extremity weakness and, occasionally, autonomic nervous system affliction manifested as bladder dysfunction also may occur.^{32,69,147} Whereas most manifestations of parenchymal CNS involvement evolve during the acute stage of TBE, paralysis resulting from radiculitis may develop up to 14 days after the onset of CNS disease.^{48,82}

As many as 5% of children with TBE experience seizures during the acute stage of TBE.^{22,48,153} Because most patients are older than 6 years and thus are unlikely to suffer from febrile seizures, these episodes probably reflect encephalitis. In adults, seizures have been observed in less than 2% of patients.^{32,68}

Extracerebral manifestations of TBE seldom are reported and are of minor clinical relevance. Mild hepatitis^{54,68} and electrocardiographic abnormalities have been described in adults.¹⁵¹ A single case of myopericarditis in a child with TBE has been reported.³³

The peripheral white blood cell (WBC) count is not altered in a characteristic way. Although it is usually in the normal range, both leukopenia and moderate leukocytosis may be found.^{48,96,147} In adult patients, several investigators observed leukopenia during the viremic prodrome and normal or moderately elevated WBC counts during the second phase of illness.^{68,77,96,99} In a report describing hematologic values during the prodromal phase of TBE, 23 of 28 (82%) patients had mild to moderate thrombocytopenia ($60\text{--}130 \times 10^9/L$), with values returning to normal during the second phase of illness.⁹⁹ Cerebrospinal fluid (CSF) analysis in children with serologically proven TBE reveals predominantly mononuclear pleocytosis in all patients. However, as with enteroviral meningitis, neutrophils may predominate during the first 1 to 3 days of illness.⁶⁴ Typically, the CSF WBC count is 100 to $1000 \times 10^6/L$.^{48,79,92,96,147,153} On occasion, lower values occur, as reported by Krausler and associates,⁷⁶ who found less than $100 \times 10^6/L$ in 24 of 75 (32%) pediatric cases. Wahlberg and colleagues¹⁵⁶ reported an absence of pleocytosis in 18% of 94 adult patients examined. Harasek⁴⁸ could not

FIGURE 176G.4 T2-weighted magnetic resonance imaging series of a 5-year-old girl with a severe course of tick-borne encephalitis. (A) Acute phase. Note the T2 hyperintensity in the right side of the thalamus, basal ganglia, and diencephalon. (B) One month later, partial recovery of T2 hyperintensity and enlargement of cerebrospinal fluid spaces can be seen. (C) Three months later, normal T2 intensity and a cerebrospinal fluid–filled cavity in the right side of the thalamus are apparent. (Courtesy David Nadal, MD, University Children's Hospital, Zurich, Switzerland.)

find any correlation between the CSF leukocyte count and the severity of clinical disease. In contrast, some investigators^{69,68,72} reported that adult patients with a high CSF white blood cell count ($>300 \times 10^6/L$) were more likely to experience a severe course of TBE and persistent neurologic sequelae. CSF pleocytosis disappears within 4 to 5 weeks of the onset of acute CNS disease. The CSF glucose concentration is normal,⁹⁶ and the protein concentration is normal or moderately elevated (<1000 mg/L),^{48,77,96,147} with evidence of dysfunction of the blood-brain barrier in most patients.⁶⁹ Electroencephalographic examination findings during acute TBE usually are abnormal and characterized by a nonspecific reduction in rhythmic background activity, bilateral periodic slowing, and, rarely, focal abnormalities.^{48,67,68} Attenuation of background activity with periodic delta groups has been shown to correlate with parenchymal CNS involvement in adult TBE patients.⁶⁷ Reorganization of electroencephalographic activity commonly lags behind clinical improvement, and abnormalities may persist for months to years.^{48,67,153}

The limited information available on magnetic resonance imaging (MRI) in children with severe TBE indicates that parenchymal lesions characteristically are located in the thalamus (see Fig. 176G.4).^{22,68,71,91,157} The diagnostic and prognostic value of neuroimaging studies in pediatric TBE has not been established as well as in adults. In adults, MRI studies may detect abnormality in approximately 20% of patients.⁶⁸ Focal lesions are more likely to be found in those with severe neurologic abnormalities⁶⁸ and are located mainly in the thalamus.^{5,10,70,97,121,154,157} Less frequently, lesions are located in the basal ganglia,^{5,68,97,121} cerebellum,^{10,68} brainstem,^{11,22,68} and anterior portions of the cervical spine.^{10,22} Available case series suggest that brain lesions visible on MRI in TBE do not appear to correlate with disease severity.¹²² However, in patients with paralysis associated with meningoencephaloradiculitis, high-resolution MRI is helpful in determining alpha motor neuron injury.⁹¹

PATHOLOGY

CNS findings are mainly those of acute meningeal inflammation and focal gray-matter encephalomyelitis. The white matter rarely is involved. Macroscopic findings include congestion of the leptomeninges and swelling and hyperemia of the cerebral parenchyma, particularly in the brainstem and cervical region of the spinal cord.^{43,112} Petechial

hemorrhages are seen in the brainstem, the anterior horns of the spinal cord, and, less consistently, the cerebellum and the anterior central region of the cortex. Histologic changes are dominated by infiltration and ganglion cell damage in the gray matter of these same areas. Changes are particularly pronounced in the anterior horns of the cervical spine (consistent with the poliomyelitis-like manifestations of paralytic courses of TBE),¹³⁸ the medulla oblongata, the cranial nerve nuclei of the pons, and the Purkinje cell layer of the cerebellum.⁴³ Inflammatory foci are characterized by lymphocytic perivascular infiltration and various stages of degenerative changes in neuronal cells. Areas of neuronal necrosis are characterized by perifocal edema, lymphocytic and neutrophilic infiltration, and, at a later stage, nodular microglial proliferation at sites of complete neuronophagia. The presence of granzyme, B-expressing, cytotoxic T cells in close contact with TBE-expressing neurons indicates that immune mechanisms contribute to tissue injury in these areas.⁴⁰ Rarely, the spinal nerve roots, spinal ganglia, and peripheral nerves are involved. Spongiform changes, particularly after protracted illness, appear as sharply defined areas of softening with minimal inflammatory reaction. In the Far Eastern form of the disease, extensive poliomyelitis of the spinal cord with destruction of anterior horn cells, particularly in the upper cervical and lower lumbar areas, and poliomyelitis of the brainstem are noted.

PATHOGENESIS

Tick-mediated inoculation of TBEV and viral replication within local dermal cells are followed by lymphatic spread to regional lymph nodes, where further replication occurs.⁶⁹ Subsequently, viremia leads to generalized infection, especially of reticuloendothelial cells, followed by secondary rounds of viremia that result in neuroinvasion. Viral penetration of the CNS occurs through microvascular capillary endothelial cells and by TBEV-infected, infiltrating mononuclear cells, without compromising the integrity of the blood-brain barrier.¹¹⁹ Envelope glycoprotein E, the immunodominant TBEV-encoded surface protein, mediates attachment to and fusion with the host cellular membrane.¹⁰² The molecular mechanisms of neural invasion by TBEV have not been elucidated in detail. Current knowledge of the molecular pathogenesis of TBEV has been reviewed elsewhere.^{51,50,49}

LABORATORY DIAGNOSIS

Because neither clinical nor CSF findings differentiate TBE from other causes of meningitis or meningoencephalitis, the diagnosis of TBE rests on demonstration of specific antibody by serologic testing. The presence of specific serum immunoglobulin M (IgM) or a significant rise in titer of specific IgG antibody in paired sera (or both) is diagnostic of TBE,^{57,58,69} unless the patient previously received TBE vaccine doses. Enzyme-linked immunosorbent assay (ELISA) has replaced complement fixation, hemagglutination inhibition, and neutralization assays in the routine laboratory diagnosis of TBE.^{56,58} ELISA technology offers increased sensitivity, reliably differentiates between IgM and IgG antibodies, and, in contrast to neutralization, uses nonviable viral antigens.^{52,129} For the detection of specific anti-TBEV IgM, an IgM-capture ELISA system has proved to be more sensitive and specific than the conventional three-layer ELISA system because high titers of specific IgG and rheumatoid factor do not interfere with IgM binding.^{52,129} With this method, specific IgM virtually always can be demonstrated during the acute illness and thereafter may persist for as long as 9 months.^{57,69,129} The highly sensitive capture ELISA format allows a determination of anti-TBEV IgM, even in serum samples obtained late during the acute illness, when high titers of specific IgG already are present. A potential problem of TBEV IgG ELISA systems is cross-reactivity with other flaviviruses, notably yellow fever virus, dengue virus, and Japanese encephalitis virus.^{29,30,114} This limitation should be considered in the interpretation of seroprevalence studies and in patients with a relevant travel or immunization history.

Specific IgM and IgG to TBEV also can be measured in CSF.^{52,129} Detection of TBEV-specific intrathecal antibody production by ELISA is highly specific for the diagnosis of TBE but somewhat less sensitive than is determination of serum IgM during the first several days of CNS disease.^{58,69} Up to 16% of patients with TBE will not have intrathecal TBEV-specific IgM detectable; therefore absence of intrathecal antibody does not exclude the diagnosis of TBE.⁵³ Intrathecal TBEV antibody assays are less widely used in clinical practice, but they may be useful if serum antibody titers fail to differentiate between infection- and vaccine-induced immunity.

Detection of virus by culture is technically feasible, but it is not used routinely in clinical practice. TBEV can be recovered from blood by viral culture, but because detectable viremia occurs during the prodromal stage (when the diagnosis of TBE seldom is considered), culture is not useful in clinical practice. TBEV may be recovered from the brain tissue of patients who died at an early stage of disease.²³ Amplification of TBEV-specific RNA by reverse transcriptase polymerase chain reaction (RT-PCR) has been established for detection of TBEV in ticks, in tick surveys as part of national surveillance systems,^{38,123} and, in humans, for individual patient diagnosis.¹⁴³ Primers that amplify the highly conserved 5' noncoding region of the TBEV genome have been shown to be sensitive and specific.¹⁴² Successful amplification of TBEV-specific RNA from blood, CSF, or brain tissue has been reported.^{24,143,152,157} However, like culture, RT-PCR usually is positive only during the prodromal stage and thus generally is not useful in clinical practice.⁶⁶

DIFFERENTIAL DIAGNOSIS

The clinical course of TBE is nonspecific in most cases, and a history of exposure to ticks in an endemic area can be elicited in 40% to 75% of pediatric patients.^{48,70,92,96,110,140,153} Because serologic confirmation of the diagnosis is not available immediately in most cases, the differential diagnosis includes a wide spectrum of diseases causing fever and CNS manifestations.

Enteroviruses are the most common cause of symptomatic CNS infection in children during the warm seasons in regions where TBE is prevalent. Fever in enteroviral infection may occasionally be biphasic,¹⁰⁸ although the durations of both the first phase and the asymptomatic interval usually are shorter than those noted in TBE.¹⁹ Routine tests of CSF do not differentiate between the two entities. Skin and mucosal manifestations are indicative of enteroviral infection rather than TBE, whereas encephalitis and myelitis can occur in both. Enteroviral meningitis is diagnosed most readily by PCR of CSF¹³⁵ or by culture

of virus from CSF and mucosal surfaces. Mumps meningitis is to be considered in the differential diagnosis in cases without parotid enlargement, particularly in areas with low rates of mumps immunization.¹⁴⁸ The diagnosis of mumps meningitis is made by viral culture of CSF or detection of specific serum IgM antibody. Although it is a rare occurrence in childhood, herpes simplex virus (HSV) encephalitis always should be considered in the differential diagnosis. Because the case-fatality rate of HSV encephalitis is greater than 90% if it is left untreated, therapy with intravenous acyclovir should be initiated without delay, if that diagnosis is thought possible. The combination of fever, which may be biphasic,¹³⁰ and localizing signs observed by neurologic examination, electroencephalographic studies, or MRI⁶⁰ suggests HSV encephalitis and rarely occurs in pediatric TBE, particularly if the temporal lobe or the orbital portion of the frontal lobe is affected. Meningeal irritation usually is absent in HSV encephalitis. The diagnosis of HSV encephalitis is confirmed by PCR of CSF.^{9,89} Epstein-Barr virus encephalitis can occur in immunocompetent children, and Epstein-Barr virus shares with TBEV a preference for causing thalamic and basal ganglia lesions.^{68,117} Other viral causes include common respiratory tract viruses such as influenza, parainfluenza, and adenovirus.

Among bacterial infections, partially treated pyogenic meningitis, encephalitis in association with *Mycoplasma pneumoniae* infection,¹³² and encephalopathy caused by *Bartonella henselae* may resemble TBE. Tuberculous meningitis runs a subacute course, and although near-normal CSF chemistry may be recorded very early in the disease, hypoglycorrachia invariably develops and CSF protein rises to high levels. CNS infection by *B. burgdorferi* is particularly important in the differential diagnosis because in Europe this pathogen and TBEV are transmitted by the same tick vectors—*I. ricinus* and *I. persulcatus*—and because one of the most prevalent European genospecies, *Borrelia garinii*, is more neurotropic than *B. burgdorferi* sensu stricto.¹³¹ In contrast to TBE, the incubation period for early neuroborreliosis in children generally is 4 to 10 weeks, high-grade fever is unusual, and most patients have cranial nerve palsy. However, several cases of concomitant infection with TBEV and *B. burgdorferi* have been reported in the literature,^{1,21,78,116} and coexistence of TBEV and *B. burgdorferi* in ticks has been documented.⁷⁵ In some cases of TBE, persistent or late-appearing limb paralysis has been suggested to be attributed to concomitant, but undiagnosed, borrelial radiculoneuritis rather than TBE-related myelitis with anterior horn involvement.⁷⁸ In this situation, diagnostic evidence of Lyme borreliosis coinfection with TBEV-associated TBE should be sought because this condition requires antimicrobial therapy.¹⁶ Seroepidemiologic and clinical evidence indicates that concomitant infection with TBEV and *Anaplasma phagocytophilum*, the agent of human granulocytic ehrlichiosis, also may occur.^{75,100}

TREATMENT

No specific antiviral therapy is available to treat TBE. However, recent studies suggest TBEV is inhibited by LCTA-949, an analog of the antibiotic teicoplanin, and the anthelmintic compound ivermectin.^{27,104} In severe cases, supportive therapy is aimed at preventing the development of sequelae related to increased intracranial pressure, seizures, and bulbar dysfunction. After the acute stage, neurorehabilitation may be necessary for patients with motor, cognitive, or emotional disturbances. Because TBE rarely causes a chronic seizure disorder, prolonged anticonvulsive therapy seldom is indicated in patients who had convulsions during acute disease.

PROGNOSIS

Approximately 4% of patients will die during the acute illness of TBE. The main risk factor for neurologic residua and a fatal outcome of TBE is advanced age.^{2,68,144} Also, patients with meningoencephaloradiculitis are more likely to have more severe and fatal illness.⁹¹

Substantial sequelae also may occur in two-thirds of children,^{48,70,80,96,139,153} and according to long-term follow-up studies of pediatric TBE patients, a variety of neurocognitive and motor sequelae may occur, including issues with short- and long-term memory, learning, executive functions, and physical impairments of gross and fine motor

skills, balance problems, and coordination problems. Children also may experience chronic headaches, fatigue, and irritability.^{34,37,151,155}

Individual cases of children, presenting more likely with meningo-encephalitis in the acute phase, show persistent neurologic damage, including hemiparesis,^{22,66,71,157} unilateral arm paresis,¹⁵⁶ epilepsy,^{66,71,128} and extrapyramidal movement disorder.⁷¹ Recent evidence, however, indicates that subtle abnormalities in attention and psychomotor skills may persist in many children for prolonged periods.¹³⁹ In adult patients, long-term neurologic defects are observed in 2% to 10% of patients with clinical evidence of parenchymal CNS involvement during the acute illness.^{2,42,68,72,156}

Risk factors for persistent sequelae have been assessed by Kaiser⁶⁸ and, by univariate analysis, include impaired consciousness (i.e., Glasgow Coma Scale score <7), ataxia, paresis, abnormal findings on MRI, CSF pleocytosis greater than $300 \times 10^6/L$, and CSF protein concentration of more than 600 mg/L. Gunther and colleagues⁴⁵ reported that encephalitic symptoms were associated with low levels of intrathecal IgM in early stages of TBE. Paresis of the extremities and ataxia are the most common persistent findings on neurologic examination.^{2,32,70,72,101,144} Much more common, however, are ill-defined manifestations such as chronic fatigue, headache, sleep disorders, memory dysfunction, and emotional disturbances, which are reported by most adults recovering from TBE and persist for months to years.^{32,90,144} In some patients, electroencephalographic findings may remain abnormal for prolonged periods, with seizure activity occasionally demonstrated.^{48,139} Most of these patients are symptom free, although epilepsy secondary to TBE has been described infrequently.^{48,111} For these reasons, children who recover from TBE should have their neurologic, cognitive, and developmental status assessed on a regular basis.

The reported case-fatality rate in adult TBE patients is approximately 1% in large series,^{2,32,42,70,72,101} with most deaths being attributed to severe bulbar encephalitis or related to underlying cardiovascular disease in elderly patients.³² Fatal outcome of TBE in children is exceedingly rare.¹⁰⁶ Fatal outcomes from TBE have been reported in transplant recipients.⁹⁵

PREVENTION

General preventive principles include avoidance of known endemic areas of TBE, use of protective clothing, and rapid removal of ticks attached to the skin. The topical repellent *N,N*-diethyl-*m*-toluamide (DEET) has a definite, albeit moderate, effect against ticks.¹³³ Because of its potential neurotoxicity, the content of DEET in products used for children should not exceed 15%.^{15,118} These measures are effective in reducing tick exposure and transmission of TBEV to some degree. Pasteurization of raw milk prevents enteric transmission of TBEV.^{4,73} Travelers should assess their risk for TBE by knowing whether the countries and regions to be visited are endemic with TBE illness, whether they will be traveling during peak (April to November) season, whether they will travel at an altitude less than 1500 m above sea level, whether the travel stay will be of long duration, whether the travel will involve tick exposure–associated activities in forests or other tick-infested areas, and whether the travelers are of advanced age or have comorbidities of illness that may put them at higher risk for severe or fatal illness with TBE.

Reliable protection, however, requires active immunization against TBE. Inactivated whole-virus vaccines are produced in Austria (Baxter), Germany (Chiron), and Russia. These vaccines are made from different central European TBEV strains; they are produced by concentrating and purifying cell culture fluid from infected chick embryo cells and consist of a three-injection immunization schedule.⁶³ Adjuvants (aluminum hydroxide) are added to the formalin-inactivated cell culture fluid. The Russian vaccine is an inactivated, unconcentrated cell culture fluid from infected African green monkey kidney cells. An inactivated, purified whole-virus vaccine produced in primary hamster kidney cell lines is now produced in China and is effective against the Far Eastern TBEV strain seen in that country.¹⁶¹ TBE vaccine is also available in the United States under investigational drug exemption to military personnel deployed in endemic areas.^{12,25}

Currently approved TBE vaccines are approved for children 12 months and older. Basic immunization consists of three doses given at 0, 1 to

3, and 5 to 12 months. Rapid immunization schedules also are available. The vaccines are immunogenic and safe.^{28,41,42,44,120,140}

Seroconversion rates for neutralizing antibodies after the first, second, and third dose are 70%, 95%, and 99%, respectively.^{81,85} Reliable protection is achieved 2 weeks after administration of the second dose.¹⁶⁴ Data on the kinetics of vaccine-induced serum antibodies led to the first recommendation for booster doses every 3 years.^{81,83} Recent data on the decay of neutralizing antibodies, however, indicate that protection may last at least 5 years in children and 10 years in adults.^{74,126,127,160} Therefore booster doses are recommended only every 5 to 10 years in some European countries. Minor adverse events (i.e., fever and local reactions) are reported by 4% to 15% of vaccinees after receiving the first dose and less frequently after receiving subsequent doses.^{83,120,163} Mostly transient neurologic adverse events temporally associated with the administration of TBE vaccine have been reported rarely.^{41,42,136,137,141} Their true incidence has not been established. Based on passive notification of adverse events, an incidence of one neurologic illness in 1 million doses of TBE vaccine has been calculated.⁵⁵ Placebo-controlled trials of vaccine efficacy have not been conducted. Observational studies in Austria using historical controls indicate that the effectiveness of the vaccine is greater than 90%.^{84,88}

In Austria, the TBE vaccine is recommended for mass immunization of all potentially exposed individuals. Since the beginning of the vaccination campaign in 1981, a dramatic reduction in nationally notified cases has been observed (Fig. 176G.5).^{88,165} Mass immunization is the probable cause of this decrease because neighboring countries (e.g., Switzerland, southern Germany, and Slovenia) reported stable or increasing numbers of cases of TBE during the same time. In these and other endemic countries of central and eastern Europe, authorities recommend immunization of school-aged children and adults who live in endemic areas and have a risk for exposure to ticks.^{22,113} In younger children, TBE vaccination is not recommended routinely because neurologic complications are exceedingly rare.^{22,92}

Specific IgG against TBEV has been used historically for passive immunization within 96 hours of exposure to ticks in endemic regions. Because of reports from some patients^{3,86} who developed a severe form of

FIGURE 176G.5 Annual number of cases of tick-borne encephalitis in Austria before and after the introduction of mass immunization in 1981 (arrow). (Data from the International Scientific Working Group on Tick-Borne-Encephalitis, <http://www.tbe-info.com/report>.)

TBE disease after immunoglobulin administration, these products have been withdrawn in many countries and are no longer recommended. These severe cases raised concern about a causative role of TBE immunoglobulin in enhancement of disease.^{8,70,71,97,154,157} Also, postexposure vaccine administration is not recommended, because of similar concern about antibody-dependent enhancement.¹⁷ Antibody-dependent enhancement, a mechanism of pathogenicity proposed in dengue hemorrhagic fever,¹⁰⁹ is a possible explanation for both phenomena,⁷¹ and although plausible, experimental data in support of this hypothesis in TBE are lacking.⁷¹

176H ■ Zika Virus Infections*

Kristina Adachi • Claudia Raja Gabaglia • Patricia Brasil • Karin Nielsen-Saines

Zika virus (also known as ZIKV) is a mosquito-borne flavivirus that was discovered in 1947 in a yellow fever sentinel rhesus monkey stationed in Uganda's Zika forest, from which it takes its name.^{111,193,299} (Figs. 176H.1 and 176H.2). Although ZIKV's history since discovery spans nearly seven decades, it was only in 2016 that ZIKV rose from obscurity and received global, household recognition as an emerging infectious disease of cataclysmic proportions. During those early years, ZIKV had only caused sporadic, denguelike infections with smaller human epidemics, most notably those reported in 2007 in Micronesia and in 2013–14 in French Polynesia and other South Pacific Islands.^{65,121,193,298,299,303}

ZIKV has emerged as a formidable opponent, posing a major threat to global health security, particularly for pregnant women and their infants.³²⁶ Some have even drawn parallels between ZIKV's potential to cause human devastation worldwide and the HIV pandemic.^{173,199} From February to November 2016, the World Health Organization (WHO) declared ZIKV a "Public Health Emergency" owing to concerns that infection in pregnancy may lead to congenital anomalies such as microcephaly and other neurologic complications.^{180,427,467} Leaders at the WHO and Centers for Disease Control and Prevention (CDC) now consider ZIKV to be the first major infectious disease associated with congenital birth defects to be discovered in more

FIGURE 176H.1 Zika forest in Uganda, where Zika virus was first isolated in 1947. (Courtesy Dr. Andrew D. Haddow, USAMRIID, Fort Detrick, MD.)

than half a century, joining a pantheon of infections such as rubella, cytomegalovirus, lymphocytic choriomeningitic virus, toxoplasmosis, syphilis, and others.^{73,88,322,332,352}

EPIDEMIOLOGY

History of ZIKV as an Emerging Infection From 1947 to the Present

Discovery of ZIKV

The known history of ZIKV^{222,257,329} begins in 1947 with three scientists: G.W.A. Dick, S.F. Kitchen, and A.J. Haddow from the Medicine, Public Health, and International Health Divisions of the Rockefeller Foundation,

*Our understanding of Zika infections has changed dramatically over the past several years. This chapter is based on the authors' review of the literature in May 2016 and again in December 2016. We highly recommend that readers refer to key reference sources (WHO, CDC, PAHO, etc.) listed at the end of this chapter for the most up-to-date information, especially with regard to epidemiology and clinical care, which are constantly changing.

FIGURE 176H.2 *Aedes* mosquito. The *Aedes* species of mosquito have been primarily responsible for the spread of Zika virus around the world. (From the World Health Organization, <http://www.portal.pmnch.org/emergencies/zika-virus/history/en/>.)

the National Institute for Medical Research in London, and the Virus Research Institute in Entebbe, Uganda.¹¹¹ They were studying yellow fever in the Zika forest, which neighbors Lake Victoria and the Entebbe-Kampala road in Uganda¹¹¹ (see Fig. 176H.1). From one of their captive, sentinel rhesus monkeys (#766) that developed a low-grade fever, they were able to isolate a new virus.¹¹¹ With serum obtained from this rhesus monkey, they inoculated adult and infant mice intracerebrally, which triggered illness after 1.5 weeks and ultimately led to recovery of a filterable virus, which we now know as *Zika virus*.¹¹¹ The following year, in 1948, the same researchers were able to demonstrate that ZIKV could also be recovered from captured, wild *Aedes africanus* mosquitoes in the same forest.^{110,111}

A few years later, in 1952, during additional investigations of yellow fever in the East African countries of Uganda and Tanzania, the first reported cases of human infection were incidentally discovered during serologic surveys of 297 residents for antibodies to multiple viruses (Zika and others such as West Nile, Bwamba fever, Semliki Forest, Bunyamwera, Ntaya, Mengo, and Uganda S viruses).⁴¹⁶ Researchers were evaluating whether antibodies to those viruses could potentially be used to neutralize yellow fever virus.⁴¹⁶ Subsequently during an investigation of jaundice and yellow fever in Eastern Nigeria, ZIKV was isolated from one patient, a 10-year-old girl with fever and headache, who was coinfecting with malaria.²⁴⁹ Serologic antibody response to ZIKV was also detected in two other patients during that investigation.²⁴⁹

After this period of fortuitous early discovery, the presence of ZIKV was acknowledged only in a few case reports and was primarily documented through serologic surveys, albeit without reports of hospitalization for severe infection or deaths. Yet, it is now apparent that unbeknownst to many, a smoldering level of human ZIKV infection was well maintained across diverse populations spanning half a century. Some have speculated that cocirculating arboviruses such as dengue and chikungunya, as well as ZIKV's propensity to cause primarily mild illness, were the primary factors that allowed it to persist and hide unnoticed for decades. Given the lack of human ZIKV outbreaks reported during this time and a handful of isolated human cases reported, it is only through retrospective phylogenetic mapping of ZIKV that has allowed researchers to trace ZIKV's temporal and geographical path from its early origins to the present. From Uganda, ZIKV appeared to have traveled across the African continent and later to Asia during the latter part of the 20th century. Evidence of ZIKV has been found in multiple additional countries, including Senegal, Sierra Leone, Ivory Coast, Burkina Faso, Nigeria, Cameroon, Central African Republic, Gabon, Ethiopia, Egypt, Kenya, Tanzania, Somalia, Pakistan, India, Thailand, Vietnam, Malaysia, Indonesia, and the Philippines, among others.* A detailed report of ZIKV human serologic surveys by year and country is available in the literature.^{206,222,301}

First ZIKV Epidemics: The 2007 Federated States of Micronesia (Yap Island) and the 2013–14 French Polynesia, New Caledonia, and Cook Island ZIKV Epidemics

It was not until 2007 that the first major human ZIKV outbreak was identified in one of the Pacific Islands known as Yap Island in the Federated States of Micronesia.¹²¹ It was estimated that 73% of the population older than 3 years of age had been infected with ZIKV, and approximately 900 or more Yap residents had illness from ZIKV infection.¹²¹ Yet, the majority of those infected with ZIKV did not appear to develop clinical disease.¹²¹ In one study of 185 suspected ZIKV cases, ZIKV was confirmed in 49 (26%) cases, whereas the other 59 (32%) were considered probable cases.¹²¹

The following year, in 2008, the first case of suspected sexual transmission of ZIKV was noted and subsequently reported in 2011.¹⁵⁶ An American researcher contracted ZIKV in Senegal and transmitted the infection to his wife upon return to the United States.¹⁵⁶ This was the first time evidence existed suggesting an arbovirus could be acquired by sexual transmission.¹⁵⁶

In 2012, researchers discovered that there were two distinct Zika viruses: the African and the Asian lineages. The Asian lineage was first documented in the Yap Island ZIKV epidemic.^{182,389} In the following years from 2013 to 2014, additional outbreaks of Asian lineage ZIKV were reported in other Pacific Islands, most notably in French Polynesia but also in New Caledonia and the Cook Islands, with later spread to other islands in the region including Vanuatu, Solomon Islands, and Easter Island.^{329,389} Phylogenetic analysis demonstrated that the French Polynesia ZIKV strain was closely related to ZIKV strains recovered from the Yap Island outbreak in 2007 and Cambodian cases seen in 2010.^{28,303}

These cases of ZIKV in the Pacific were first identified by the French Polynesia public health authorities during investigations of a major dengue outbreak. French Polynesia, best known for its most populated island, Tahiti, is a country comprising five archipelagos with 67 inhabited islands. During that time, French Polynesia and other surrounding Pacific islands reported approximately 28 new outbreaks of cocirculating arboviruses (dengue, chikungunya, and ZIKV), with reports of more than 120,000 people infected with at least one of those three arboviruses.³⁸⁹ The largest ZIKV outbreak occurred in French Polynesia, where it was estimated that 11% of the population was infected, with 8746 suspected ZIKV cases and an estimated 30,000 seeking medical attention due to ZIKV concerns.^{105,227,380,389} It also included 1400 confirmed cases in New Caledonia and 932 cases in the Cook Islands.³⁸⁹ This epidemic in the Pacific exported ZIKV cases to other countries: from Tahiti to Norway, from French Polynesia to Japan, from Thailand to Germany and Canada, and from Indonesia to Australia.^{152,231,232,433,457}

The resulting investigations of the Pacific region ZIKV outbreaks, particularly the outbreak in French Polynesia, formed the basis of our early understanding of clinical aspects of ZIKV infection, including its potential to be transmitted from mother to child (perinatal transmission) as well as its potential to cause clinical complications.^{33,64,65,314} Before these investigations, cases of ZIKV infections had been described as primarily self-limited, nonspecific viral infections characterized by mild symptoms. However, during the French Polynesia ZIKV outbreak, 42 cases of Guillain-Barré syndrome (GBS) were reported, which was the first time concerns were raised about ZIKV's potential to cause neurologic complications.^{64,314,389} In addition, recently conducted retrospective analyses revealed that congenital anomalies such as microcephaly and other cerebral malformations also occurred with increased frequency during the ZIKV outbreak in French Polynesia, strengthening evidence of ZIKV as a cause of congenital anomalies.^{32,68} The outbreak was also significant because it increased awareness about the potential for ZIKV infection to be asymptomatic and the possibility of ZIKV blood-borne transmission. More than 42 (3%) of the 1505 asymptomatic blood donors were found to be positive for ZIKV, and only one-fourth of these donors later developed symptomatic ZIKV infection.^{34,301,302}

ZIKV's Rapid Global Expansion: Epidemics in Brazil, Other Latin American Countries, and Beyond

The first case of autochthonous circulation of ZIKV in the Americas was actually reported in February 2014 by Chile with regard to ZIKV transmission on Easter Island, an island located in the southeastern

*References 10, 96, 111, 137, 144, 187, 206, 208, 222, 254, 257, 268, 286, 301, 319, 320, 329, 388, 398, 412, 471.

region of the Pacific.^{331,337} The following year in March 2015, the Brazilian Ministry of Health gave its first notification to the WHO about clusters of an unknown acute, exanthematic, denguelike illness that was occurring in the northeastern region of the country since late 2014.^{66,482} From February to April 2015, they reported more than 7000 cases of a clinically mild infection, of which only 13% were positive for dengue virus; and tests for other infections in the differential diagnosis, including chikungunya, measles, rubella, parvovirus B19, and enterovirus, were all negative.^{222,257,329} A few months later, in May 2015, the Brazilian National Reference Laboratory identified that this mysterious infection being transmitted in the state of Bahia in Brazil was, in fact, ZIKV.^{63,257,334,482} Brazilian public health authorities promptly notified the Pan American Health Organization (PAHO) and the WHO. The PAHO then released an epidemiologic alert to its member states about the potential for additional ZIKV outbreaks in regions where *Aedes* mosquitoes were present.^{134,257,329}

Subsequently, the ZIKV strain in Brazil was shown to be of the Asian lineage and appeared to have originated from French Polynesia.^{92,141,168} Some have speculated that it may have been introduced by tourists from the Pacific Island regions attending the World Cup Soccer Event in Brazil from June to July 2014 or the Va'a World Sprint Championship Canoe Race in Rio de Janeiro, Brazil in August 2014, where the four Pacific region countries of French Polynesia, New Caledonia, Cook Islands, and Easter Island competed.^{141,297} Another study suggested that the virus might actually have reached Brazil a year earlier, being introduced in mid-2013 during a prequalifying soccer World Cup event, the 2013 Fédération Internationale de Football Association (FIFA) Confederations Cup.¹⁴¹

By mid-July 2015, the ZIKV situation in Brazil had become more worrisome, with reports suggesting that increased neurologic disorders such as GBS were being seen in patients following a recent history of ZIKV infection.^{15,45} Apart from Brazil, by October 2015, additional reports of ZIKV were surfacing from Colombia and Cabo Verde, an island on the northwest coast of Africa also known as Cape Verde.^{257,271,329,334} By October 2015, the ZIKV epidemic had grown substantially in Brazil, with 14 states reporting autochthonous ZIKV transmission, which coincided with new concerns about the discovery of a substantial increase in microcephaly cases identified at birth, particularly in the state of Pernambuco.^{42,257,277,329,331,334} In the months following, Brazil declared a national public health emergency over growing concerns about an association of ZIKV and microcephaly with 1248 reported cases, more than 20 times greater than expected.^{42,257,276,281,329,337,361}

Shortly after this announcement, progress was made in establishing evidence linking the ZIKV epidemic with congenital anomalies such as microcephaly in Brazil.^{42,361,406} ZIKV was recovered from the amniotic fluid of two pregnant women whose fetuses were found to have microcephaly on prenatal ultrasound; the ZIKV genome was also recovered from tissue and serum samples of an infant with microcephaly.^{59,150,204,224} An official investigation by the PAHO and the WHO response team was also launched.³³⁶ Other alerts were issued in the Americas about ZIKV's potential to cause both congenital anomalies such as microcephaly and neurologic complications such as GBS. By the end of 2015, it was estimated that there were nearly 210,000 suspected and confirmed ZIKV cases in Brazil, but numbers may have been as high as 440,000 to 1.3 million cases.^{128,193,335,405}

Subsequently, further additional evidence from Brazil strengthened links of ZIKV with congenital anomalies.⁴⁰⁶ Microcephaly of four fetuses/infants (two miscarriages and two early neonatal deaths) was described among four women with rash and fever during pregnancy and placenta and fetal/infant brain tissue testing positive for ZIKV RNA and immunohistochemistry.¹²⁷ Reports from ophthalmologists in Brazil also described severe ocular anomalies, including macular atrophy, accompanying microcephaly in three infants.^{448,450} By the end of January 2016, the consequences of ZIKV in Brazil were astounding, with more than 3893 suspected cases of microcephaly and 1708 cases of GBS reported.²⁵⁷ On February 1, 2016, in response to the concerns of the emerging ZIKV epidemic in Brazil and its complications, the WHO Director General issued a declaration that ZIKV constituted a "Public Health Emergency of International Concern" in an effort to mobilize governments, public health, and scientific community into action worldwide.^{180,467}

TABLE 176H.1 Countries and Territories in the Americas With Reported Congenital Syndrome Associated With Zika Virus

From World Health Organization and Pan American Health Organization. Regional Zika Epidemiological Update (Americas). 2016. http://www.paho.org/hq/index.php?option=com_content&view=article&id=12390&Itemid=42090&lang=en.

As of December 29, 2016, there were 2289 confirmed cases of ZIKV congenital syndrome in Brazil, which includes cases of microcephaly and other congenital malformations, with most (approximately 90%) having occurred in the northeast region of the country.^{335,338} Interestingly, this exponential increase in microcephaly cases in northeastern Brazil contrasts to the lower numbers of potential ZIKV congenital syndrome cases in other countries of the Americas^{335,338} (Table 176H.1).

After establishing itself in the *Aedes* mosquito populations in Brazil, ZIKV transmission rapidly spread.^{193,326} Some have cited two major factors behind ZIKV's "explosive spread" throughout Latin America, the Caribbean, and other regions: namely the unmatched ability of *Aedes aegypti* to flourish in urban settings, and the lack of preexisting immunity to ZIKV among resident populations.³²⁶ Outside of Brazil, locally acquired ZIKV infection was being reported in many other Central and South American countries, including Suriname, El Salvador, Guatemala,¹⁰⁷ Mexico,¹⁷⁹ Paraguay, and Venezuela.^{257,329} During the end of 2015 to early 2016, ZIKV spread to additional countries, including Panama,¹⁶ Honduras, French Guiana, Martinique, Puerto Rico, Maldives, Guyana, Ecuador,⁴⁸⁰ Barbados, Bolivia, Haiti, Saint Martin, the Dominican Republic, Saint Croix (US Virgin Islands), Nicaragua, Curaçao, and Jamaica.^{257,329} The list of affected countries further expanded by February 2016 to include Samoa, Bonaire, Aruba, Trinidad and Tobago, Saint Vincent, Grenadines, and Argentina, as well as Kosrae and other Federated States of Micronesia, Dominica, and Cuba by March 2016.^{257,329} In addition, during that time, reports of increasing cases of GBS in conjunction with ZIKV transmission were also surfacing first from El Salvador and then from Venezuela, Suriname, and Honduras.^{257,329} By November 2016, more than 18 countries and territories in the Americas had reported cases of GBS following confirmed ZIKV infection.⁴⁶⁸ Furthermore, other global regions, including Africa (Guinea-Bissau) in July 2016, as well as Southeast Asia, began reported locally acquired ZIKV cases, with two confirmed cases reported in Vietnam in April 2016.⁴⁶⁹ In September 2016, additional countries apart from Vietnam in the Western Pacific

Region reported ZIKV cases, including Singapore, Philippines, Malaysia, and Thailand.⁴⁶⁹

Based on WHO surveillance as of December 2016, the level of global ZIKV transmission is staggering. Recent ZIKV transmission has been reported in more than 75 countries, which include at least 48 countries

in the Americas with new ZIKV circulation since 2015.^{141,328,339,352,470} (Figs. 176H.3 and 176H.4). In light of the ZIKV epidemic in Brazil and the rest of the Americas, the decision to continue to hold the August 2016 Rio de Janeiro Olympic Games was also a source of considerable controversy.^{177,267} However, ZIKV had declined considerably by that

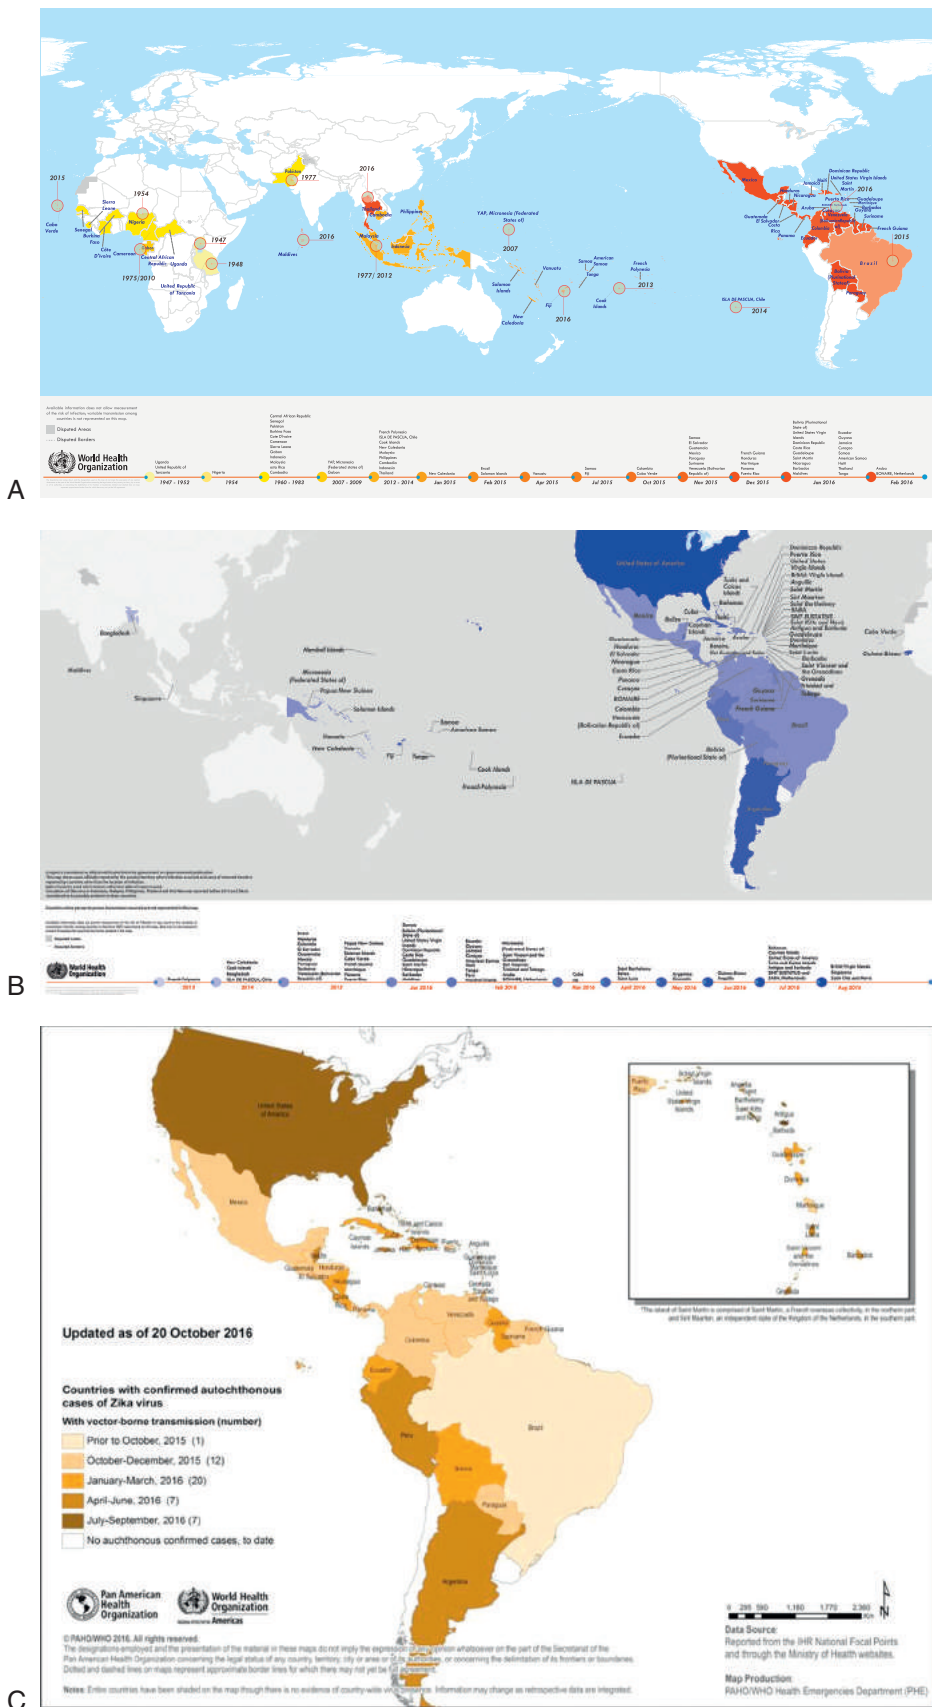

FIGURE 176H.3 (A) The figure is a timeline from the WHO that shows ZIKV global distribution from 1947 to early 2016. (B) The figure shows more recent ZIKV transmission from 2013 to August 2016. (C) The figure focuses on countries with demonstrated autochthonous (vector-borne) ZIKV transmission in the Americas from 2015 until November 2016. FIGURE 176H.4 All countries and territories with active Zika virus (ZIKV) transmission as of December 16, 2016. The figure shows countries and territories with active ZIKV transmission according to the CDC. (From <http://www.cdc.gov/zika/geo/index.html>; Centers for Disease Control and Prevention. Zika virus: all countries and territories with active Zika virus transmission. 2016. <http://www.cdc.gov/zika/geo/active-countries.html>.)

time in Brazil, and no ZIKV cases were reported as a result of Olympic Games attendance.

ZIKV cases in the United States and US territories significantly increased during the June to August 2016 travel months.⁹⁷ Other contributing factors included the first US cases of locally transmitted ZIKV by the end of July 2016 in Miami, Florida as well as additional reports of locally transmitted ZIKV in Brownsville, Texas by the end of November 2016.^{74,246,262,264} Updated as of December 28, 2016, from the CDC's ArboNET, there have been 216 locally acquired mosquito-borne cases of ZIKV (210 in Florida and 6 in Texas) and 4592 travel-associated ZIKV cases, including 38 sexually transmitted cases and 1 laboratory-acquired case in the United States from 2015 to 2016.^{375,378} However, in the US territories of American Samoa, Puerto Rico, and the US Virgin Islands, there have been a total of 132 travel-associated cases and 34,841 locally acquired cases, the majority occurring in Puerto Rico, which reported a large increase in ZIKV cases starting in July 2016.^{375,378} Evaluation of 16,522 ZIKV-suspected patients in Puerto Rico from November 2015 to July 2016 found that more than 5351 (32%) had laboratory evidence of ZIKV infection.⁵ It has been estimated that ZIKV may have infected approximately 25% of the population in Puerto Rico, including 6000 to 11,000 pregnant women.¹⁶¹ (For updated information on the United States and US territories, refer to the CDC website at <http://www.cdc.gov/zika/geo/united-states.html>.)

Given concerns about ZIKV infection, particularly for pregnant women, the US CDC and other worldwide public health authorities have issued alerts to women who are pregnant or planning to conceive, to avoid or postpone travel to countries with active ZIKV transmission. Travel warnings were issued for South Florida and Brownsville, Texas in the United States and for the majority of countries and territories in Latin America, the Caribbean, Cape Verde in Africa, Oceania, and the Pacific Islands, as well as Singapore, where a cluster of locally transmitted cases was noted at the end of August 2016^{74,260,327,362} (see Fig. 176H.4). Since September 2016, the CDC and WHO also acknowledged Southeast Asia (including Cambodia, Laos, Malaysia, Maldives, Philippines, Thailand, Vietnam) as another region with active ZIKV transmission, but the risk for transmission is thought to be lower given prior population immunity.^{252,275,376,456,471} After the Americas, the Asia-Pacific region ranks second in countries affected by ZIKV, with 19 countries reporting ZIKV cases.¹²⁶ The WHO has also issued warnings regarding the likely increasing spread of ZIKV to Australia,¹⁸⁴ China,⁴⁸⁸ Japan,⁴¹⁰ other Pacific Islands, and Southeast Asian countries.^{126,436} Epidemic levels of ZIKV transmission in resource-limited countries in Asia-Pacific and Africa may be of particular concern given the 2.6 billion people living there, as well as socioeconomic and environmental conditions that may facilitate ZIKV spread.^{37,400}

Areas with active ZIKV transmission are being continually updated on the CDC website (<http://wwwnc.cdc.gov/travel/page/zika-travel-information>; <http://www.cdc.gov/zika/geo/active-countries.html>) (see Fig. 176H.4).

Transmission of ZIKV

Arbovectors: Aedes Mosquitoes

The *Aedes* species of mosquitoes are primarily responsible for the rapid global spread of ZIKV because the mosquito bite is considered the predominant mode of ZIKV transmission to humans (see Fig. 176H.2). The mosquito acquires the virus during its blood meal from a viremic person or animal, and the virus replicates in the salivary glands of the mosquito.³⁰¹ Then, during a subsequent blood meal, the mosquito introduces saliva infected with ZIKV into a new host.³⁰¹ Mosquito saliva not only is important in transmitting the virus but also may be relevant in the establishment of viral infection. Recent work in experimental mice infected with Semliki Forest virus, a mosquito-borne alphavirus relative of the chikungunya virus, has shown that the *A. aegypti* saliva potentiates viremia 10-fold compared with viral infection alone, by causing inflammation attracting neutrophils and myeloid cells to the mosquito biting site.³⁵⁷ Since ZIKV was isolated from the *A. africanus* mosquito back in 1948 in the forests of Uganda,^{110,111} it has been subsequently detected in several other sylvatic (forest-dwelling) *Aedes* mosquito species, including the *Aedes apicoargenteus*, *Aedes furcifer*,

Aedes luteocephalus, *Aedes taylori*, and *Aedes vitattus*, among others.^{142,301} Lists of ZIKV by year, country, and *Aedes* species are available in the literature.^{142,301}

An early laboratory study from 1956 demonstrated *A. aegypti*'s ability to transmit ZIKV to mice and monkeys, and ZIKV was later isolated from *A. aegypti* mosquitoes in Malaysia in 1969. However, *A. aegypti*'s critical role in ZIKV transmission has only been recognized in more recent epidemics. Other *Aedes* species, including *Aedes hensilli* (Yap Island epidemic) and *Aedes polynesiensis* (French Polynesia epidemic along with *A. aegypti*), were also found to be important transmitters during the outbreaks in the Pacific.^{142,176,187,190,240,244,254,464,473}

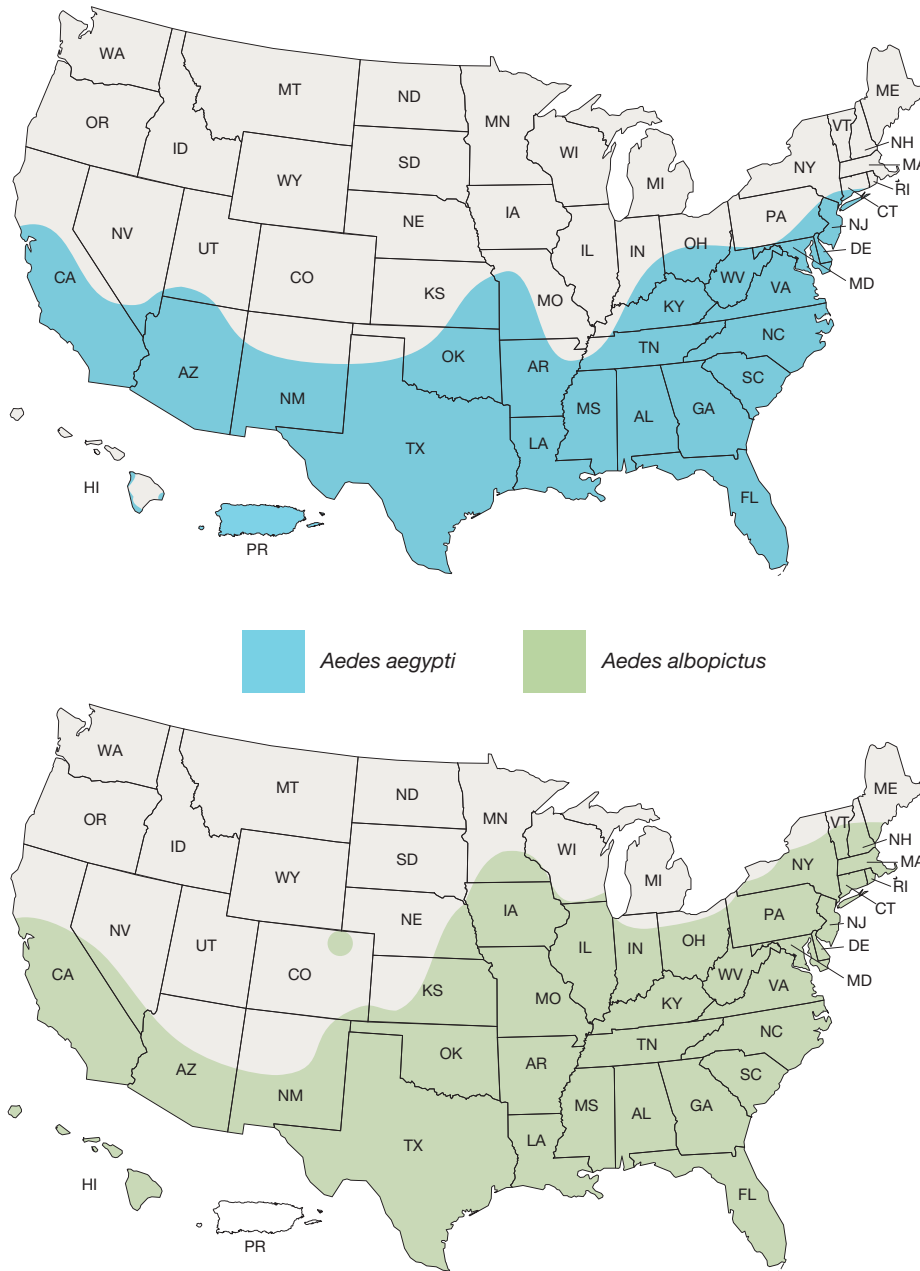

Currently, the "citified" *Aedes* species, *A. aegypti* and *Aedes albopictus* (Asian tiger mosquito), appear to be the dominant players responsible for the recent explosive spread of ZIKV throughout Latin America and the Caribbean.³²⁶ Although these mosquitoes originated in the African continent, they were introduced to the Americas through human (slave) migration by way of ships coming to the New World.^{294,360} As a result, some species of *Aedes* mosquitoes (*A. aegypti* and *A. albopictus*) are considered endemic in southern and southeastern regions of the United States, posing the greatest risk of infection for poor urban Gulf Coast communities^{199,460} (Fig. 176H.5). It should be noted that mosquito classifications also grossly reflect their breeding sites, and *Aedes* mosquitoes differ from other mosquitoes such as *Anopheles* (vector of malaria) that prefer to breed in permanent water sources (swamps or lakes) and *Culex quinquefasciatus* (vector of West Nile virus) that preferentially breeds in storm or septic drains with organic matter.¹⁶⁹ Termed the "gothic cockroach" of mosquitoes by some, *A. aegypti* is a small black mosquito with white banded legs that has a natural affinity for dark colors and spaces along with an uncanny ability to thrive in close proximity to humans.^{169,326} Flourishing in densely populated urban environments, they attack in the day (morning and afternoon) and even prefer to breed in artificial containers with water, which may be as small and as seemingly innocuous as discarded bottle caps or plastic wrappers.^{169,187,326,364}

A recent study of mosquitoes in Mexico has provided additional evidence confirming suspicions that *A. aegypti* has been the primary species of mosquito linked with ZIKV transmission in the Americas because they were unable to detect ZIKV in other frequently encountered tropical, urban-dwelling mosquitoes (i.e., *Culex* species such as *C. quinquefasciatus*).¹⁷⁹ Similar findings were also reported in other studies in the United States and Brazil.^{147,463}

The true, definitive natural hosts and reservoirs of ZIKV still remain under investigation, but nonhuman primates and humans are believed to be the main reservoirs, with anthropocentric (human-to-vector-to-human) transmission characterizing outbreaks.^{187,364} ZIKV antibodies have been detected in many primates in Africa and Asia, and ZIKV epizootic (nonhuman animal) transmission cycles, which included monkeys, were reported in Uganda and Senegal.³⁰¹ ZIKV has also been isolated from two species of monkeys, *Cercopithecus aethiops* and *Erythrocebus patas*.^{86,142} However, other studies have detected ZIKV antibodies in several animals, including rodents, goats, bats, sheep, and others.^{96,182,301,460} Although some have even suggested that bats may play a role in sylvatic ZIKV transmission cycles,²¹⁴ uncertainty still exists about whether other, nonprimate animal species can serve as ZIKV reservoirs.^{86,142,183,187,190}

Nevertheless, it is clear that ZIKV appears to have a remarkable ability to adapt and persist in new ecological environments. In April 2016, researchers reported detection of ZIKV in monkeys in Northeastern Brazil and Ecuador.³²⁶ Furthermore, ZIKV has been detected in wild *A. albopictus* mosquitoes in Mexico, which is worrisome because of its ability to survive in even cooler climates than other *Aedes* species.³²⁶ A more recent study has also suggested that vertical transmission of ZIKV in *A. aegypti* mosquitoes may occur, which may further facilitate ZIKV's survival during adverse environmental conditions.⁴³⁵ The incubation period of ZIKV in the mosquito host is 10 days, whereas the mosquito itself has a lifespan of 30 days. Therefore, hypothetically, the mosquito would have two-thirds of its lifetime at best to successfully transmit the infection.

Refer to Fig. 176H.4 and the CDC website for updated information about all countries and territories with active ZIKV transmission⁷⁵ (<http://www.cdc.gov/zika/geo/index.html>).

Aedes aegypti mosquitoes are more likely to spread viruses like Zika, dengue, chikungunya and other viruses than other types of mosquitoes such as *Aedes albopictus* mosquitoes.

These maps DO NOT show

- Exact locations or numbers of mosquitoes living in an area
- Risk or likelihood that these mosquitoes will spread viruses

These maps show

- CDC's best estimate of the potential range of *Aedes aegypti* and *Aedes albopictus* in the United States
- Areas where mosquitoes are or have been previously found

FIGURE 176H.5 Estimated range of *Aedes aegypti* and *Aedes albopictus* mosquitoes in the United States and the potential for Zika virus spread. Maps have been updated from a variety of sources. These maps represent the Centers for Disease Control and Prevention's best estimate of the potential range of *A. aegypti* and *A. albopictus* in the United States. Maps are not meant to represent risk for spread of disease. (From <http://www.cdc.gov/zika/pdfs/zika-mosquito-maps.pdf>. Last updated by the CDC on August 2, 2016.)

Other Modes of Transmission

Apart from mosquito-vector transmission, other modes of transmission of ZIKV have been documented, including case reports of sexual transmission, transfusion-associated transmission (which includes at least four cases of probable transfusion-related ZIKV transmission in Brazil),^{27,209,290,302,307,447} and perinatal transmission.^{32,33,44,59,68,450}

Suspected cases of ZIKV sexual transmission (including male-to-female, male-to-male, and female-to-male sexual transmission) were reported from French Polynesia, as well as at least 12 other countries, including France, Germany, Italy, New Zealand, and the United States, in returning travelers.* Updates from the CDC as of December 28,

2016, have now documented more than 38 cases of ZIKV from sexual transmission in the United States.^{196,378} ZIKV may be transmitted sexually before, during, or after symptom onset, and in known cases from unprotected sexual activity (vaginal, anal, or oral).³⁶³ At least one case and possibly another case (male-to-female sexual transmission) have also suggested the potential for ZIKV to be sexually transmitted from an asymptomatic carrier.^{49,160} There are no studies evaluating the relevance of sexual transmission in the human population, but based on mathematical modeling studies, sexual transmission may account for a small portion of ZIKV transmission (3%), although it may be a significant contributor to prolonging the ZIKV epidemic and serving as an additional risk factor for ZIKV transmission.¹⁶⁴ Likewise, some sexually transmitted infection (STI) experts have suggested that sustained sexual transmission of ZIKV in the population seems unlikely given the relatively short infectious duration of ZIKV compared with other STIs.^{13,477}

*References 13, 98, 100, 115, 156, 158, 160, 189, 196, 266, 288, 306, 309, 340, 341, 442, 451.

ZIKV has been detected in semen^{22,251,309,390,442} as well as spermatozoa,²⁵³ breast milk,¹²³ urine,^{35,38,174,205,309,391,410,486} and saliva.^{30,35,38,247,305,309,413,434,472} ZIKV has also been identified from the genital tract of women (cervical mucus, endocervical, and genital swabs tested positive for ZIKV by reverse transcriptase polymerase chain reaction [RT-PCR]).^{98,308,379} Similarly, ZIKV has also been detected from vaginal fluid in nonhuman primates.¹²⁰ Prolonged ZIKV shedding in the urine and saliva has also been reported for 29 to 91 days.^{155,259,309} Some studies have suggested even more prolonged virus detection in semen for up to 188 days after symptom onset.^{22,189,251-253,259,309,353,363,372} Interestingly, ZIKV was detected in the semen for up to 39 days in a man, who was asymptotically infected.¹⁶⁰ ZIKV has also been detected in semen for 69 days in a vasectomized man.¹⁸

The epidemiologic relevance of detection of ZIKV in these bodily fluids, apart from semen and the female genital tract,^{22,98,251,379,390,442} and the risks for transmission have not been yet determined, although replication-competent (infective) virus has been isolated from patient urine and saliva.³⁸ A case of secondary nonsexual ZIKV transmission (presumably through unprotected contact with sweat or tears) occurred after visiting a hospitalized patient with extremely high levels of ZIKV viremia and has raised new and unanswered questions about the infectious risks of contact with bodily fluids in those with severe ZIKV infection.^{48,428} Although mucocutaneous transmission of flaviviruses is rare, animal models have demonstrated its possibility, and nosocomial mucocutaneous transmission of dengue has also been reported in at least one instance.^{79,80,428}

Although ZIKV viremia typically may range from a few days to 1 week, some case reports did suggest that ZIKV viremia has been detected in patients 10 to 16 days after onset of symptoms.^{30,155,480} However, in pregnant women with fetal abnormalities detected in pregnancy, ZIKV viremia may be prolonged because ZIKV has been detected in the blood as long as 10 weeks (70 days) after infection.^{119,444} A study of five pregnant women in the United States with prolonged ZIKV viremia (up to 46 days after symptom onset) found that only one infant had evidence of fetal ZIKV infection.²⁶⁹ In another report of a congenitally infected infant, ZIKV viremia was noted 67 days after birth, and ZIKV was detected from urine and saliva on his 54th day of life.³¹⁶

Importantly, ZIKV has been detected in as many as 1.1% blood donors in regions with active ZIKV transmission, such as Puerto Rico, which has led to subsequent efforts to protect the blood donation supply through US Food and Drug Administration (FDA) recommendations, which include deferral of donations from high-risk individuals, screening of blood donors, and special management of blood products.^{228,353} In addition, given modes of ZIKV transmission, organ and tissue transplantation, fertility treatment, and breast-feeding may all pose theoretical risks for ZIKV transmission.³⁶³ (Refer to the later section on ZIKV Prevention for further details about prevention efforts from vector and nonvector transmission standpoints.)

VIROLOGY AND PATHOGENESIS

Virology of ZIKV

Viral Classification and Structure

ZIKV is classified within the mosquito-borne clade X and *Flavivirus* cluster within the *Flavivirus* genus and *Flaviviridae* family^{178,230,301} (Fig. 176H.6). It is one of 73 viruses and includes 53 distinct species within the *Flavivirus* genus, which have been classified based on molecular-based taxonomy into appropriate clusters, clades, and species.^{85,178,301,356} However, only one other virus, Spondweni virus, is in ZIKV's clade, with which it shares about 70% of its nucleotides.¹²⁵ Other closely related viruses are Ilheus, Rocio, and St. Louis encephalitis viruses.^{85,190,230} Other well-known viruses within the *Flaviviridae* family are yellow fever, Japanese encephalitis, West Nile, dengue, and hepatitis C viruses. Of these, ZIKV shares approximately 60% of its nucleotides with Japanese encephalitis, West Nile, and dengue virus.¹²⁵

Similar in structure to other viruses in the *Flaviviridae* family, ZIKV is an icosahedral-shaped, enveloped single-stranded positive-sense RNA virus (+ssRNA). In fact, with almost atomic resolution (3.7 Å), the three-dimensional cryo-electron microscopy (cryo-EM) structure of ZIKV has now been demonstrated and has highlighted structural

FIGURE 176H.6 Colorized electron micrograph depicting Zika virus (ZIKV) particles in red. The ZIKV particles are 40 nm in diameter with an outer envelope and an inner dense core. (From CDC/Cynthia Goldsmith, <http://phil.cdc.gov/phil/details.asp>.)

similarities with other viruses within the *Flaviviridae* family.^{26,226} It is approximately 40 to 45 nm in diameter and composed of 10,794 nucleotides, which encode 3419 amino acids.^{85,109,190,229,230,397} It has two noncoding regions (5' and 3') as well as a single long open reading frame that encodes a polyprotein: 5'-C-prM-E-NS1-NS2A-NS2B-NS3-NS4A-NS4B-NS5-3'.^{144,355}

This ZIKV polyprotein is cleaved into three smaller structural proteins that form the virus particle—the capsid (C), precursor of membrane (prM), and envelope (E)—as well as seven other nonstructural (NS) proteins—NS1, NS2A, NS2B, NS3, NS4A, NS4B, and NS5—which are involved with genome replication and polyprotein and cellular process modulation.^{52,144,355} The 53-kDa envelope (also known as E protein) is the major surface protein of ZIKV and a key component in the viral replication cycle that allows for binding and cell membrane fusion.¹⁴⁴ Its nucleocapsid is surrounded by a lipid bilayer derived from the host membrane with E and M envelope proteins. As seen through high-resolution cryo-EM studies, the ZIKV E envelope protein shows resemblance to other flavivirus E proteins, such as Japanese encephalitis and West Nile viruses, which are also known to exhibit neurotropism.²²⁶ The E protein is the most common target for neutralizing antibodies, and antibody responses to the envelope protein are often protective.⁴²²

NS1 is a nonstructural protein seen in ZIKV and other flaviviruses and functions as a virulence factor that is important for viral replication and also has immune-modulatory roles, including immune evasion. Although the overall ZIKV NS1 structure is similar to other flaviviruses, crystallographic studies of the ZIKV NS1 have shown an extended hydrophobic and polar surface different from West Nile and dengue serotype 2 that may affect cellular membrane attachment.^{52,476} NS5, which is the largest ZIKV protein, has dual functions with RNA-dependent RNA polymerase (C-terminal) activity and RNA capping owing to its methyltransferase (N-terminal) activity.¹⁴⁴ The 3'-noncoding region may also have roles in translation, genome stabilization, RNA packaging, cyclization, and cellular/viral factor recognition functions.¹⁴⁴ The ZIKV helicase is considered an important component in viral replication, and some hypothesized that it may be a target for an antiviral drug after recent determination of the crystal structure of the ZIKV helicase was reported.^{207,438} Other studies have also suggested that polyamines (small, positively charged ornithine-derived molecules) are important for ZIKV replication.²⁹²

Flaviviruses are known to be inactivated by high temperatures (>56°C for at least 30 minutes), pH ≤6, ultraviolet-light and gamma radiation

and are susceptible to 30 minutes of contact with disinfectants like 1% sodium hypochlorite, 2% glutaraldehyde, 70% ethanol, 3% to 6% hydrogen peroxide and 3% to 8% formaldehyde, TRIzol, and Buffer AVL.^{23,36,55,139,171,304} Subsequent preliminary studies on ZIKV inactivation have also determined that certain types of disinfectants used in laboratories typically will inactivate ZIKV.²⁹⁵ Loss of ZIKV infectivity was observed after exposure to all types of alcohols, 1% hypochlorite (typically used to inactivate viruses in BSL-2/3 laboratory liquid waste), 2% paraformaldehyde, 2% glutaraldehyde, ultraviolet-light radiation, temperatures of 60°C or higher, and pH ≥ 12 or pH ≤ 4 .²⁹⁵ These studies also observed that dried ZIKV could remain infectious for more than 3 days and that standard contact barriers such as intact nitrile and latex gloves are protective.²⁹⁵

ZIKV Phylogeny and Genetics

Although ZIKV's origins can be traced back to East Africa, evolutionary patterns in ZIKV sequencing have been described.^{233,352} The full genome of the original ZIKV from Uganda (MR 766 prototype) was sequenced in 2007, as were genomes of ZIKV strains from other outbreaks in Brazil, Cambodia, Central African Republic, French Polynesia, Guatemala, Malaysia, Nigeria, Puerto Rico, Senegal, Thailand, and Yap, which are available in GenBank.^{229,301}

The initial phylogenetic analyses done after the Yap Island outbreak in 2007²³³ identified several ZIKV lineages, including two African lineages (eastern and western) and one Asian lineage, which are referred to as the East African (Uganda prototype), West African (Senegal), and Asian (Yap) strains.^{144,233,301,352} Subsequently, full genome sequencing identified two primary ZIKV lineages, the African lineage (including Nigeria, Senegal, and Uganda strains) and the Asian lineage (including Malaysia, Yap, and Cambodia strains); the study suggested that ZIKV likely arrived in the Yap Islands by way of Southeast Asia.^{182,301} An additional phylogenetic analysis of 43 ZIKV strains from 1947 to 2007 confirmed earlier findings of African (MR-766 prototype Uganda and Nigeria clusters) and Asian (Yap and Malaysian) ZIKV strains.^{144,301} It was suggested that ZIKV likely appeared in East Africa in the 1920s, traveled to West Africa, and then dispersed to Asia in the 1940s.^{144,301} Sequencing of ZIKV in Brazil has suggested that it is of the Asian lineage, likely originating from French Polynesia.^{41,92,141,168} Although African strains were typically responsible for asymptomatic or mild infection, the Asian strain, which may also cause asymptomatic or mild infection, has been largely responsible for the reported congenital anomalies. Some have speculated that recombination events of ZIKV may have contributed to changes in its pathogenicity.^{144,301,344,462}

Other unresolved questions involve the pathogenicity, particularly neuropathogenicity, of different ZIKV strains. A recent study has reported a shared mutation of amino acids at NS5, a nonstructural ZIKV protein, in isolates from Colombia, Mexico, Panama, and Martinique.⁸ It has been suggested that this NS5 mutation may form a "Latin American" clade of ZIKV that appears to be distinct from the virus isolated from Brazil and has been speculated that it may affect ZIKV's neutropism.⁸ In addition, one study comparing African (strain from Central African Republic) and Asian lineages has demonstrated higher infectivity of human astrocytes and neural stem cells, cell death, and antiviral response of the Central African strain; the researchers hypothesized that the older African MR-766 original strain used in the experiments may have lost its neurovirulence because of serial in vitro passages compared with other African ZIKV lineage strains.⁴¹¹

Of note, the WHO has recently developed a ZIKV candidate reference strain (ZIKV strain PF13/251013-18) for the development of nucleic acid amplification tests (NAATs).⁴⁴¹ The reference strain was isolated from serum from a French Polynesian patient with ZIKV in 2013 and related to ZIKV strains recently detected in Central and South America, the Caribbean, and the Pacific regions.⁴⁴¹

Viral Pathogenesis

Current understanding about ZIKV's pathogenesis is limited, although rapidly evolving. As with other mosquito-transmitted flaviviruses, it is believed that after ZIKV is transmitted through the mosquito's bite. The virus initially sustains itself by replicating locally in dendritic cells at the site of inoculation before spreading to lymph nodes and more

distant sites of the body.^{108,190} Because dendritic cells, dermal fibroblasts, and epidermal keratinocytes may be infected with ZIKV, these cells in humans are thought to be important in ZIKV's pathogenesis.^{186,301} One study from the 1980s has suggested that ZIKV may also be able to replicate in the host cell nucleus because its antigens have been detected in cell nuclei; this finding is unusual for flaviviruses, which are known to replicate in the cellular cytoplasm.^{54,190}

Early animal studies provided some basic insight into ZIKV's pathogenesis in humans. Apart from the initial rhesus monkey (#766) that developed mild fever from ZIKV infection and thereby enabled ZIKV's discovery, other rhesus monkeys did not develop symptoms of acute infection after being inoculated with the virus, even after demonstrating viremia.^{109,111} Interestingly enough, other small animals inoculated intracerebrally with ZIKV, including cotton rats, guinea pigs, and rabbits, also did not demonstrate apparent symptoms of ZIKV infection.¹⁰⁹ However, both rhesus monkeys and rabbits were able to demonstrate an antibody response to ZIKV.^{109,111} More contemporary studies of rhesus monkeys inoculated with a recent 2016 ZIKV clinical isolate demonstrated that monkeys did develop fever and viremia.^{120,243,342} ZIKV was excreted in multiple bodily secretions, including urine, saliva, tears, semen, and vaginal secretions, and evidence of ZIKV was detected in the central nervous system (CNS) (brain and spinal cord) and other organs (lymph nodes, parotids, stomach, liver, kidney, bladder, spleen, intestines, testes and other male and female reproductive tissue, and heart).^{120,243,342} Detection in saliva and urine was prolonged for approximately 4 weeks, and repeat challenge with ZIKV after primary infection resulted in protection from subsequent infections.³⁴²

Other fascinating observations in early animal studies included reports that ZIKV was highly neurotropic in mice and was only recovered from brain tissues of infected mice.^{109,111} Upon autopsy of ZIKV-infected mice, these early studies observed neuronal degeneration, cellular infiltration, Cowdry type A inclusion bodies, and "softening" of brain tissue, with young mice demonstrating the most extensive brain lesions.¹⁰⁹ In addition, although mice of all ages were found to be susceptible to infection when inoculated intracerebrally, only mice younger than 2 weeks of age became sick when infected intraperitoneally with ZIKV.¹¹¹ Of note, one study in mice also reported lesions in tissues other than the CNS induced by ZIKV, including skeletal myositis, myocarditis, and lung edema.⁴⁶⁴ In contrast to these findings in mice, other early animal studies of rhesus monkeys, cotton rats, guinea pigs, and rabbits did not demonstrate ZIKV's neurotropism.^{109,111,301}

Additional in vitro studies have investigated nonhuman cell lines that support ZIKV infection. Nonhuman cell lines, including nonhuman primate (Vero and LLC-MK2), pig (PK-15), rabbit (RK-13), hamster (BHK21), and chicken (DF-1) cell lines, supported productive ZIKV replication.⁷⁸

Human in Vitro Cellular Studies and Histopathology From Neonatal Autopsies

ZIKV replication and its cytopathic effects have also been observed in several human cell lines, including placental (JEG-3), neuronal (SF268), muscle (RD), retinal (ARPE19), pulmonary (Hep-2 and HFL), colonic (Caco-2), and hepatic (Huh-7) cell lines.⁷⁸ In addition, several other human cell lines, including prostatic (LNCaP), testicular (833KE), and renal (HEK) cell lines, have also shown increased ZIKV viral load without cytopathic effects.⁷⁸

Further in vitro studies have also suggested that ZIKV may exhibit a wide range of maternal and fetal tissue and cell tropism and have helped elucidate potential mechanisms of ZIKV maternal-fetal intra-uterine transmission.^{130,383,430} ZIKV has the capability of infecting various umbilical cord (mesenchymal stem cells), human placental cell, and chorionic villus cell types (cytotrophoblasts, endothelial cells, fibroblasts, Hofbauer cells [also known as primary human placental macrophages]) in chorionic villi, amniotic epithelial cells and trophoblast progenitors in amniochorionic membranes, which express the ZIKV cofactor (TIM1).^{130,213,383,430} One study demonstrated that ZIKV had particular affinity for replication in placental macrophages (Hofbauer cells) and that ZIKV viral replication coincided with induction of type I interferon (IFN), proinflammatory cytokines, and antiviral gene expression, but with minimal cell death.³⁸³ Overall, these results suggest that ZIKV may

cause fetal infection by initially infecting placental cells, which disrupts the placental barrier.³⁸³ ZIKV can infect these cells from early, mid, and late gestation, suggesting not only placental but paraplacental transmission.⁴³⁰ Target inhibitors of TIM1 may also have the potential to inhibit ZIKV infection at the uterine-placental interface.⁴³⁰

One study also found that serially passaged ZIKV strain (MR-766) was able to infect human neural progenitor cells and increase cellular death.^{279,431} Likewise, the Asian/Brazilian ZIKV strain has also been shown to infect human cortical progenitor cells and lead to increased cell death with disruption of proliferative zones and cortical brain layers.^{89,245,321} ZIKV may also damage cranial neural crest cells, which are important precursors of skull bone and cartilage, which leads to increased cytokine production and abnormal in vitro neurodevelopment.³¹ Furthermore, others have suggested that high AXL expression, which may serve as a ZIKV cellular entry receptor in neural stem cells, may be one of the factors contributing to ZIKV's observed neurotropism.^{279,312} A link between ZIKV neural progenitor cells and the upregulation of toll-like receptor 3 (TLR3) has been suggested and may lead to cell death and abnormal regulation of neurogenesis, axon guidance, and cell differentiation.⁹⁵

Pathologic evaluation of fetuses and infants with congenital ZIKV infection has also confirmed findings of direct ZIKV cytopathic effects primarily localized to the brain.⁴⁰⁷ Histopathology of congenital ZIKV syndrome from spontaneous abortions and neonatal autopsies has demonstrated microcalcifications, scattered microglial nodules, cell degeneration, and necrosis of brain tissue, along with identification of ZIKV antigens in neurons and glial cells.²⁵⁵ Placental pathology has shown villous edema, increased Hofbauer cells, and ZIKV antigens in Hofbauer cells in the chorionic villi.²⁵⁵ The lack of significant inflammatory response in the fetal or infant brain, along with distinguishing viral cytopathic features, appear to be more characteristic of ZIKV (as well as congenital rubella infection) as opposed to other congenital infections such as cytomegalovirus and herpes simplex virus.²⁵⁵

Recent Insight Into ZIKV's Pathology, Including Experimental Animal Model Studies (Mice and Nonhuman Primates)

One important discovery has been the development of ZIKV mouse models because immunocompetent mice are typically resistant to ZIKV challenge. However, mice lacking type I IFN receptors, either knockouts (genetically deficient) or treated with antibodies that block these receptors, are susceptible to ZIKV infection.¹⁹⁷ One study has reported that type I IFN signaling-deficient mice infected with ZIKV early in pregnancy can lead to infection of placental trophoblasts, and hence to placental damage and fetal demise,²⁷⁸ a finding previously reported in human observational studies.⁴⁴ Researchers have also demonstrated that the Brazilian ZIKV strain can infect murine fetuses and lead to intrauterine growth restriction, including signs of microcephaly, mimicking what was previously described in humans.^{44,89} Other studies of pregnant mice have shown that ZIKV can replicate in the vaginal tract, and pregnant mice infected vaginally with ZIKV during early pregnancy can lead to fetal growth restriction and fetal brain infection.⁴⁷⁸

Another study investigated the effect of ZIKV infection in several types of knockout mice, with differences in IFN receptors and abilities to produce IFN- α and IFN- β . Neurologic disease was observed and high ZIKV viral loads were detected in the brain, spinal cord, and even the testes, which appears to have relevance to both neurodevelopmental defects seen in human fetuses and ZIKV's ability to be transmitted sexually.²³⁷ A recent study reported that ZIKV (Asian strain SZ01) was able to replicate efficiently in the mice embryonic brain by targeting neuronal progenitor cells, which led to cell cycle arrest, apoptosis, and inhibition of neuronal progenitor cell differentiation.²⁴⁵ Similar findings in other murine studies and human cells have also suggested that undifferentiated neurons are very susceptible to ZIKV infection,^{47,202} especially during periods of rapid brain growth.²⁰⁰ Furthermore, ZIKV-infected mice brains were smaller, had larger ventricles, and had a thinner cortex, which appears to be consistent with the microcephalic phenotype observed in ZIKV-infected human fetuses and infants.²⁴⁵ Apart from reproducing fetal brain pathology in mice models and human in vitro cell studies, ZIKV inoculation of pregnant nonhuman primates (pigtail macaque) has also produced ZIKV-associated fetal brain pathology

with periventricular lesions in occipital and parietal lobes, cerebral white-matter hypoplasia, periventricular white-matter gliosis, and axonal and ependymal damage.⁶

Mouse studies have also demonstrated that ZIKV infection in adult mice can infect multiple parts of the eye (iris, retina, optic nerve) and can lead to conjunctivitis, panuveitis, and neuroretinitis, with high levels of ZIKV detected in the eye, lacrimal glands, and tears.²⁸⁰ ZIKV studies in mice have demonstrated that ZIKV may persist in the testes, preferring to infect spermatogonia, primary spermatocytes, and Sertoli cells, and epididymis of male mice and resulting injury including induction of cell death may lead to decreased testosterone and sperm production.¹⁷⁵

Other Studies Providing Insight Into ZIKV's Pathogenesis (ZIKV and Dengue Antibodies)

Researchers have also been interested in investigating whether prior exposure to dengue may affect ZIKV's pathogenesis given similarities of ZIKV to dengue (differences of 41% to 46% in the amino acid sequence of envelope proteins of dengue and ZIKV, whereas differences of 30% to 35% have been noted between dengue serotypes).¹⁰² A theory that has been used to explain dengue hemorrhagic complications that may occur after secondary infections with different dengue serotypes is antibody-dependent enhancement (ADE), which can lead to higher viral loads.¹⁰² This occurs because cross-reactive but nonneutralizing antibodies may bind to other dengue serotypes and facilitate entry through Fc- γ receptors present on monocytes and macrophages (primary viral replication sites) and thereby lead to increased viral replication.^{125,185} Some preliminary in vitro studies have also suggested that plasma immune to dengue may also lead to ADE and enhance ZIKV replication.^{102,219} However, at this time epidemiologic studies have not suggested dengue antibody enhancement of ZIKV infection.¹²⁵

Although little is known about the protective antibody responses to ZIKV, antibodies to other flaviviruses have been known to result in lasting, lifelong immunity to subsequent infection with the same virus.⁴²⁹ Some studies have suggested that convalescent ZIKV-immune sera has the potential to neutralize various ZIKV strains (South American, Asian, and early African ZIKV strains).^{117,487} Other studies have even demonstrated conserved epitopes between ZIKV and dengue that are targets for cross-neutralizing antibodies.^{26,429} Specifically, human monoclonal antibodies (reactive to the envelope dimer epitope 1) from dengue patients can neutralize all four dengue serotypes as well as ZIKV in cell cultures and can even be protective in murine models.⁴²⁹ In contrast, another interesting study characterizing the antigenic specificity of antibodies generated from patients that had been infected by ZIKV only, or coinfecting with dengue virus, found that antibodies to NS1 were typically ZIKV specific, whereas those reactive to the E protein domain I/II (ED I/II) did not neutralize ZIKV and dengue and instead strongly enhanced ZIKV and dengue infection, whereas EDIII or quaternary epitope ZIKV antibodies provided the best ZIKV protection.⁴²⁴

CLINICAL MANIFESTATIONS AND COMPLICATIONS

Acute ZIKV Infection

As with many other infections, ZIKV may cause an acute febrile, exanthematous illness that is typically clinically indistinguishable from many other infections, especially other arboviral infections such as dengue and chikungunya, which are transmitted by the same *Aedes* mosquito species.^{44,58,121,148,460} The exact incubation period has not been conclusively established for ZIKV but has been generally considered to be anywhere from 3 days to 2 weeks, which has its basis in other flaviviruses and mosquito studies.^{151,187,352,354,363,394}

The WHO has developed interim case definitions for any person infected with ZIKV.³³⁰ A suspected case is considered to be "a person presenting with rash and/or fever and at least one of the following signs or symptoms: (1) arthralgia or (2) arthritis or (3) conjunctivitis (nonpurulent/hyperemic)."³³⁰ The CDC suspected case definition includes an epidemiologic linkage and clinical criteria with one or more of the following, not explained by another diagnostic etiology: (1) acute onset of fever,

FIGURE 176H.7 Clinical manifestations of Zika virus in pregnant women in Rio de Janeiro, Brazil. (A) Maculopapular rash on the face. (B) Conjunctival and palpebral erythema. (C) Retroauricular lymphadenopathy. (D) Conjunctival injection with prominence of vasculature. (E) Rash on the legs, with a lacy reticular pattern. (F) Maculopapular rash on the inner arm. (G) Edema of the foot, which the patient reported was painful. (H) Blanching macular rash on the gravid abdomen. (From Brasil P, Pereira JP Jr, Moreira ME, et al. Zika virus infection in pregnant women in Rio de Janeiro. *N Engl J Med*. 2016;375[24]:2321-2334.)

(2) maculopapular rash, (3) conjunctivitis, (4) arthralgia, (5) complications of pregnancy (fetal loss or fetus or neonate with congenital microcephaly, intracranial calcifications, other structural brain or eye abnormalities, other congenital CNS-related abnormalities such as clubfoot or joint contractures), or (6) GBS or other neurologic manifestations.^{373,374}

As highlighted by the WHO and CDC suspected case definitions of ZIKV, the most commonly reported symptoms in adults include rash, transient fever, arthralgia, and conjunctivitis^{97,332,374} (Fig. 176H.7). From what has been learned from studies of patients from the Pacific Island region (Yap Island, French Polynesia, and others) as well as from Brazil and other countries in Latin America, acute ZIKV infection is typically considered mild.^{44,179,332} Fever is present in less than one-third of cases and is low grade and short lived, and the infection tends to subsist for about 2 to 7 days.^{332,44}

The exanthem of ZIKV is typically described as a nonspecific, diffuse, macular or maculopapular eruption appearing 3 days to 2 weeks after initial infection¹⁴⁰ (see Fig. 176H.7). The rash often starts on the trunk and descends to include the lower extremities, usually sparing palms and soles.^{44,106} Of note, other reports have emphasized variability in rash presentation, which may be more morbilliform or scarlatiniform, may begin on the face before spreading to the extremities, and may include the palms and soles in rare cases.¹⁴⁰ One case report described a patient with a ZIKV exanthem of the abdomen, trunk, and face,

marked by erythema and edema of the malar region of the face.^{41,44} Pruritus generally accompanies the exanthema, and desquamation may be seen after the rash subsides.^{44,49,140} Occasionally, gum bleeding and petechiae, including palatal petechiae, and oral blisters or ulcers have been observed in some patients.^{24,41,44,65,106,140,152,156,428} Skin biopsies have shown mild and focally moderate perivascular lymphocytic infiltrate in the upper dermis.¹⁰⁶

Profuse tearing has also been described in one patient with ZIKV conjunctivitis.⁴²⁸ Other symptoms, such as abdominal pain, diarrhea, emesis, and pharyngitis, are less common on presentation but have been reported.^{24,189,428} Lymphopenia, neutropenia, thrombocytopenia, and elevation in liver enzymes also appear less frequently but have been reported in the literature.^{24,155,189,275,428} Respiratory findings are generally not part of ZIKV's clinical presentation.

Definitive diagnosis of ZIKV is difficult based on clinical features alone, especially given considerable overlap in presenting features and transmission regions for other arbovirus such as chikungunya and dengue^{16,58,91,138,146} (Table 176H.2). Some have even coined the term *ChikDenMaZika syndrome* to describe the diagnostic conundrum of predominant arboviral infections in Latin America (chikungunya, dengue, Mayaro virus [a togavirus], and ZIKV) with similar presenting symptoms.^{241,346} Yet, some symptoms may be more or less common features of ZIKV compared with dengue and chikungunya. For instance, fever

Primarily adapted from a Centers for Disease Control and Prevention Presentation by Ingrid Rabe,³⁶³ "Zika Virus: What Clinicians Need to Know," a Clinician Outreach and Communication Activity (COCA), Call, Atlanta, GA, January 26, 2016. With similar tables also noted in references 21 and 138.

tends to be a less prominent feature of ZIKV infection compared with the other two, with which fever tends to be higher and more prolonged.^{138,363} Arthralgia is a much more prominent symptom in chikungunya, in which it occurs more frequently, affects multiple joints, and tends to be more severe, long lived, and debilitating than in ZIKV.¹³⁸ Thrombocytopenia with facial edema or complications of hemorrhage and shock often has been suggestive of a diagnosis of dengue and is not characteristic of ZIKV.³⁶³ In addition, rash is much more frequently observed with ZIKV; conjunctivitis is not typically seen with dengue, unless hemorrhagic, and is less frequently seen with chikungunya than with ZIKV.³⁶³ (See Table 176H.2 for further detail on a comparison of clinical features of ZIKV, dengue, and chikungunya.)

It should also be noted that some studies have also indicated the potential for other arboviral coinfections in as many as 13.3% to 20.5% of patients,⁴⁵⁹ including ZIKV with dengue^{58,124,453} and ZIKV with chikungunya.^{58,401,480} There have even been reports from Colombia and Nicaragua of patients infected simultaneously with all three arboviruses: ZIKV, chikungunya, and dengue.^{453,459}

ZIKV Presentation From the Yap Island Case Series

In 2007, one of the earliest and largest case series of ZIKV infection was performed from 49 laboratory-confirmed and 59 probable cases from Yap Island in the Federated States of Micronesia.¹²¹ The symptomatic attack rate from Yap Island among those infected with ZIKV was estimated to be 18% (95% confidence interval [CI], 10–27%).^{121,363} The most common symptoms reported were rash (90%) with a median duration of 6 days, subjective fever (65%), arthralgia (65%) with a mean duration of 3.5 days, and nonpurulent conjunctivitis (55%).¹²¹ Other frequently reported symptoms were headache (45%), retroorbital pain (39%), myalgia (48%), edema (19%), and vomiting (10%).¹²¹ All of the ZIKV infections were considered mild; none of the patients required hospitalization, had serious complications such as hemorrhagic symptoms, or died.¹²¹ (Table 176H.3).

ZIKV Presentation From Several Case Series From Brazil and Other Countries

A study from Rio de Janeiro, Brazil of 119 PCR-proven adult cases of ZIKV in 2015 corroborated the early findings from Yap Island that ZIKV is primarily a self-limited, viral illness.⁴¹ Early in the infection, the most commonly reported symptoms were rash (97%), primarily maculopapular with a mean duration of 5.5 days; pruritus (79%); prostration (73%); headache (66%); and arthralgia (63%) with a mean duration 9 days. Interestingly, fever was only observed in 36% of patients and was often transient (≤ 1 day).⁴¹ Other, less common findings included

low back pain (51%), retroorbital pain (45%), and lymph node enlargement (41%), particularly in cervical and retroauricular areas,¹⁸¹ but generalized lymphadenopathy was also observed.⁴¹ Less than one-fourth of patients (21%) reported mild hemorrhagic symptoms such as petechiae or mild bleeding from mucosal sites.⁴¹ Median leukocyte count (4590 cells/mm³), hematocrit (41.2%), and platelets (201,000 cells/mm³) were not significantly impaired in this cohort⁴¹ (see Table 176H.3). These presenting ZIKV symptoms corresponded to those seen in another Rio de Janeiro cohort of patients by the same group of investigators, but the second report was exclusive to pregnant women,⁴⁴ as well as another smaller retrospective review of ZIKV cases in 2015 in Rio de Janeiro by another group⁷⁶ (see Table 176H.3 and Fig. 176H.7).

These studies from Brazil, as well another study from Puerto Rico, underscore that the use of the term *Zika fever* may be a misnomer because many patients infected with ZIKV do not have fever.^{41,44,76,330,437} This finding was probably best exemplified in the case study of pregnant women from Rio de Janeiro, Brazil, in which fever was only seen in 28% of women and, if present, was typically low grade and transient.⁴⁴ Another important clinical feature highlighted by these studies in Brazil is the frequency of pruritus in ZIKV infections, which may help distinguish ZIKV from other arboviral infections such as dengue and chikungunya, in which pruritus appears less frequently,⁴¹ although a case of severe protracted pruritus for 3 weeks secondary to chikungunya has been reported in the literature.⁹³ In the case series of ZIKV-infected pregnant women, pruritus was observed in nearly all women (90–96%) and accompanied rash.^{43,44}

Although the largest case series of acute ZIKV infection are from Yap Island and Brazil,^{121,41,44,121,485} similar findings of this nonspecific, mild viral clinical presentation have been reported in other countries, including Mexico,²¹⁰ Thailand,⁵³ and Nicaragua,⁴⁵⁹ as well as in the majority of other case reports of travelers returning from Colombia,²⁹¹ Puerto Rico,¹⁰⁶ Thailand,^{152,201,410,433} Maldives,²²⁵ French Polynesia,^{231,481} Dominican Republic,¹²² and Suriname.¹²² In addition, most ZIKV-confirmed cases in Americans acquired from travel abroad have also been either asymptomatic or have demonstrated only mild clinical disease.⁹⁷ Smaller case series of patients presenting with acute ZIKV infection have also been published from Mexico, Panama, and Brazil (Sao Paulo).^{16,146,179} A summary table of some of the presenting features of smaller case series since the discovery of ZIKV is available in the literature.¹⁴⁶

Acute ZIKV Infection in Children

Similar to the WHO definition of a ZIKV infection in any person, the CDC has also released recommendations specific to pediatric patients regarding when to suspect acute ZIKV disease in an infant or child younger than 18 years. This includes having at least two or more clinical manifestations of fever, rash, conjunctivitis, or arthralgia and meeting criteria for ZIKV exposure.¹⁵¹ Similarly, because maternal-to-child transmission of ZIKV in pregnancy or at delivery is also possible, acute ZIKV disease should also be considered during the first 2 weeks of an infant's life among those with mothers meeting ZIKV exposure and clinical criteria.¹⁵¹ (ZIKV exposure criteria are discussed further in the ZIKV evaluation and management section).

Apart from those with in utero ZIKV exposure, relatively few reports of children with ZIKV have been published.^{12,19,124,151,192,249,318,320} Based on clinical information collected in 2007 from the Yap Islands, which included children, it has been suggested that children have similar symptoms as adults (fever, macular or maculopapular rash, arthralgia, and conjunctivitis) but generally experience more mild ZIKV infection and have lower reported attack rates than adults.^{121,151} In sentinel studies of ZIKV surveillance in Rio de Janeiro, very few nonadolescent children with symptomatic ZIKV infection were identified compared with adults (P. Brasil, personal communication, 2016). It is likely that in prepubertal children, ZIKV may be more frequently asymptomatic than in adults.

One brief review of six publications of 10 children with ZIKV infection from various regions of the world, including Cambodia, Colombia, Indonesia, New Caledonia, Nigeria, and the Philippines, also described clinical features of children with ZIKV in the literature from 1954 to 2016.^{12,19,124,151,192,217,249,318,320,354} The children ranged in age from 3 to 16 years, but the illness duration was less than 1 week and consisted

of some of the common nonspecific findings of ZIKV, such as fever, malaise, headache, and myalgia, that have been reported.²¹⁷ However, in that brief review, gastrointestinal complaints (abdominal pain, nausea, vomiting, diarrhea) were more frequently reported (seven of 10 children), and rash was not seen.^{151,217} Three fatalities in children (all female teenagers from Brazil and Colombia) have also been reported^{19,24,191} (for further details, see the later section on **Potential Complications Following ZIKV Infection**) (Table 176H.4).

Similar findings were noted in the initial unpublished data collected by the CDC in 2016 for eight children and the more recent updated version that now includes 158 cases of travel-acquired ZIKV among children younger than 18 years (range, 1 month to 17 years of age).^{151,172}

Almost all of the children with ZIKV had rash (82%), about one-half had fever (55%), and more than one-fourth had conjunctivitis (29%) and/or arthralgia (28%).¹⁷²

Other reported symptoms included myalgia, abdominal symptoms (vomiting and diarrhea), retroorbital pain, and sore throat.¹⁷² No complications such as meningitis, encephalitis, septic shock, GBS, or death were noted. However, two children (aged 1 and 4 years) were hospitalized for what appears to be more minor concerns, such as cough, fever, and poor oral intake¹⁷² (see Table 176H.4).

The presentation of ZIKV disease in neonates acquired from perinatal transmission near or at the time of delivery is also unclear apart from what is known from two reported cases.^{33,151} In these cases, the mothers

TABLE 176H.4 Pediatric ZIKV Cases in the Literature

Study	Year	Country	No. of Pediatric Cases	Age of Patient (s)	Signs/Symptoms	Other Comorbidities	Outcome	Other Comments
Macnamara et al. ²⁴⁹	1952	Eastern Nigeria	1	10	Fever, headache	Malaria coinfection	Complete recovery	—
Olson et al. ²⁵⁰	1977, 1978	Central Java, Indonesia	5	12	Fever (high), malaise, dizziness, GI complaints (abdominal pain, constipation)	—	Unknown	Zika virus cases in this study differ from in others because of high fever, no rash, and GI complaints reported in all patients
			12	12	Fever (high), malaise, dizziness, GI complaints (anorexia, abdominal pain, constipation), hypotension	—	Unknown	
			13	13	Fever (high), malaise, GI complaints (anorexia, abdominal pain, constipation), hypotension	—	Unknown	
			14	14	Fever (high), conjunctivitis, dizziness, arthralgia, myalgia, GI complaints (diarrhea), hematuria	—	Unknown	
Duffy et al. ¹²¹	2007	Yap Island, Micronesia	Not specified	Included some children ≥3 y, number not specified	Fever (high), malaise, chills, dizziness, GI complaints (anorexia, abdominal pain vomiting, diarrhea), leg pain	—	Unknown	Infection generally more mild than in adults and lower attack rates than in adults, although specific comparisons of presentation of children and adults not available
					For cohort that included children and adults: fever, rash, conjunctivitis, arthralgia most common; also reports of myalgia, headache, retroorbital pain, edema, vomiting	—	Complete recovery	—
Heang et al. ¹⁹²	2010	Kampong Speu Province, Cambodia	1	3	Fever, headache, sore throat, cough	—	Complete recovery	—
Alera et al. ¹²	2012	Cebu City, Philippines	1	15	Fever, conjunctivitis, headache, myalgia, GI complaints (abdominal pain, anorexia, nausea, vomiting), sore throat	—	Complete recovery	—
Besnard et al. ³³	2013, 2014	French Polynesia	2	Infant	Asymptomatic	—	Complete recovery	Zika virus perinatal transmission. Infants born to women with Zika had symptoms shortly before (2 days) or after (3 days) delivery
				Infant	Rash, thrombocytopenia	Pregnancy complicated by gestational diabetes and IUGR noted in second trimester, caesarean delivery. Infant with hypotrophy and hypoglycemia, neonatal jaundice, and low birth weight	Complete recovery	

Dupont-Rouzeyrol et al. ²⁴	2014	New Caledonia and French Polynesia	1	14	Fever, headache, arthralgia, myalgia, asthenia, mild thrombocytopenia and leukopenia	Dengue coinfection	Complete recovery	—
Arzuza-Ortega et al. ¹⁹	2015	Malambo, Northern Colombia	1	15	Fever, malaise, headache, arthralgia, myalgia, GI complaints (abdominal pain and jaundice)	Sickle cell disease (Hb SC)	ICU for ARDS, hemothorax, hepatic necrosis, splenic sequestration, and death	Suspected that ZIKV triggered vasoocclusion crises given history of sickle cell disease
Sarmiento-Ospina et al. ⁴⁰²	2015	Tolima, Central Colombia	1	2	Fever, altered mental status, jaundice, hepatomegaly, splenomegaly, severe abdominal pain, thrombocytopenia, mucosal hemorrhage, anemia, dehydration	Autopsy revealed probable acute leukemia (lymphoblastic)	ICU for DIC, respiratory distress, shock, and death	
Brazil Ministry of Health ¹⁹¹	2015	Brazil	1	16	Headache, nausea, petechiae	—	Likely encephalitis and death	—
Azevedo et al. ²⁴	2016	Brazil	1	16	Headache, fever, malaise, myalgia, rash, and later hemorrhagic findings of petechiae, epistaxis, hematuria, vaginal bleeding, ecchymoses, mild hepatosplenomegaly, thrombocytopenia, anemia	—	Hypovolemic shock and death	—
Mecharles et al. ²⁷⁰	2016	Guadeloupe	1	15	Headache, conjunctivitis 7 days followed by left hemiparesis, paresthesia, urinary retention, T4 sensory bilateral level	—	Lesions cervical and thoracic spinal cord consistent with acute myelitis; able to walk unassisted after methylprednisolone for 5 days	Zika virus detected serum, urine, and CSF
Fleming-Dutra et al. ¹⁵¹	2016	US (travel acquired)	8	Not specified	All with rash and ≥1 other sign/symptom such as fever, arthralgia, or conjunctivitis	—	—	—
Goodman et al. ¹⁷²	2015–2016	US (travel acquired)	158	Median age 14 y	82% had rash, 55% with fever, 29% conjunctivitis, 28% arthralgias	—	2 hospitalized; no cases of meningitis/encephalitis, GBS, and no fatalities	
Meltzer et al. ²⁷⁴	2015–16	Israel (travel acquired)	1	2	Not specified but had first occurrence of febrile seizures with normal CSF, neurologic exam, and brain MRI	—	Developed recurrent seizures 3 mo later	

ARDS, Acute respiratory distress syndrome; CSF, cerebrospinal fluid; DIC, disseminated intravascular coagulation; GBS, Guillain-Barré syndrome; GI, gastrointestinal; ICU, intensive care unit; IUQR, intrauterine growth restriction. developed ZIKV symptoms either near delivery (2 days prior) or immediately after delivery (3 days after).³³ One infant was symptom free, and the other had a rash and thrombocytopenia, but both made full recoveries without any issues^{33,151} (see Table 176H.4). It is known from reports of perinatal transmission of other arboviruses that infection during this period may range from asymptomatic infection to severe infection that may include a neonatal sepsislike presentation with fever, thrombocytopenia, and hemorrhagic complications in those with dengue and chikungunya, as well as reports of rash, meningitis, or encephalitis in those with West Nile virus infection.^{151,162,166,315,359} Of note, the CHIMERE study of infants with perinatal chikungunya exposure (in utero exposure) on the French Reunion Island in the Indian Ocean also found high rates of neonatal encephalopathy and global developmental delay, as well as some cases of microcephaly.¹⁶⁷

Potential Complications Following ZIKV Infection

Excluding the special circumstance of ZIKV infection in pregnancy, the prognosis following ZIKV infection is generally considered favorable, with most of those infected making a full recovery without any lasting sequelae. In fact, a review of 2382 confirmed or probable ZIKV cases in the United States found that only 65 (3%) required hospitalization.⁴⁶¹ However, some reported complications have been observed in patients following acute ZIKV infection.⁵⁷ Unusual but reported symptoms that have been seen after acute infection include short-term impairments in hearing, described as having a “dull and metallic” quality, dysgeusia (abnormal taste), recurrent nightmares, seizure disorder, hypertensive iridocyclitis, uveitis, unilateral acute maculopathy, and rare genitourinary symptoms, including hematospermia and prostatitis.^{152,153,156,163,274,297,348,432,465} A positive antinuclear antibody test was also reported in a ZIKV-infected patient with exacerbation of severe immune thrombocytopenia, but whether it can lead to other autoimmune diseases such as lupus is for the present time unknown.⁴⁸⁴

In contrast to the hemorrhagic complications that may follow infection with dengue virus, hemorrhagic complications such as hematomas and severe thrombocytopenia (including immune thrombocytopenic purpura with mucosal [palate and vaginal], subcutaneous bleeding, and gross hematuria) after infection with ZIKV are considered rare.^{5,61,82,206,215,300,402,409,426,481,484} In a case report of two ZIKV patients in Puerto Rico, both presented with bloody buccal mucosal lesions, which developed the day after resolution of their fever and rash.⁴⁰⁹ Both were found to have severe thrombocytopenia (1000 and 2000 platelets/ μ L).⁴⁰⁹ One recovered after receiving intravenous immunoglobulin, whereas the other died after complications from multiple hemorrhages.⁴⁰⁹ Based on these recent observations, some have hypothesized that the rare cases of thrombocytopenia seen in patients with acute ZIKV appear to be different than those that complicate dengue infections.⁴⁰⁹

At least 10 cases of death have been reported in adult patients with ZIKV without GBS.⁴²⁸ Cases of reported death from ZIKV included a patient from the United States,^{428,461} four patients from Brazil,^{24,191,419} one from Puerto Rico,^{5,409} and four from Colombia. Of these was a 2-year-old Colombian child with altered mental status, hepatomegaly, and thrombocytopenia, which evolved to disseminated intravascular coagulation, respiratory distress, and shock.^{402,409} Another was a 30-year-old Colombian woman with ZIKV infection that was complicated by severe thrombocytopenia, leukopenia, and later intracerebral and subarachnoid hemorrhages, sepsis, acute respiratory distress, seizures, and shock.⁴⁰² Autopsy revealed probable leukemias in the child and woman.⁴⁰² Another fatality was reported in a 15-year-old teenager with underlying sickle cell disease (hemoglobin SC disease), who was infected with ZIKV and presented with fever, abdominal pain, myalgia, and jaundice; her infection likely triggered vasoocclusion crises that then caused severe acute respiratory distress, hemothorax, hepatic necrosis, and severe splenic sequestration, which ultimately led to her death.¹⁹ Regarding the Brazilian females who died from ZIKV, two were teenagers, including one that presented with thrombocytopenia, anemia, and hemorrhagic manifestations and died of hypovolemic shock, whereas the other was believed to have encephalitis; another was a young woman with thrombocytopenia, hemorrhages, and pneumonia.^{24,191,419} The other fatal case was a Brazilian man with rheumatoid arthritis and lupus,

which is described in the next section on Special Populations With Acute ZIKV.²⁴ The patient from the United States was a 73-year-old man who had recently completed radiation therapy for prostate cancer; he died from septic shock with multiple-organ failure from ZIKV after presenting with tachypnea, tachycardia, abdominal pain, pharyngitis, conjunctivitis, diarrhea, fever, and myalgias after a trip to Mexico.^{428,461} ZIKV serum testing showed extremely high levels of viremia with 2×10^8 genome copies per milliliter.⁴²⁸

Special Populations With Acute ZIKV Infection (HIV-Infected and Other Immunosuppressed Patients)

It is currently unknown whether people with HIV infection or other immunocompromised conditions have a higher risk for acquiring ZIKV infection, are more likely to have symptomatic infection, or suffer from more severe or complicated infection.³⁶⁹ For other arboviruses such as dengue virus, yellow fever virus, or West Nile virus, the risk for an HIV-infected person acquiring one of these viruses is the same as the general population, but there have been some reports that indicate that HIV-infected adults with severe immunosuppression may have more complications from dengue virus.^{194,216,345,369,439} Three cases of ZIKV infection have been reported in HIV-infected adults in Brazil, and all had mild infection.^{60,369}

A fatal ZIKV case was reported in a 36-year-old Brazilian man with rheumatoid arthritis and lupus on chronic daily prednisone, who presented with severe denguelike symptoms and respiratory distress.²⁴ A small series of four patients in Brazil with renal and liver transplants that acquired acute ZIKV infection noted that none of these patients presented with rash or conjunctivitis, but they demonstrated various constellations of symptoms ranging from fever, myalgia, headache, and abdominal symptoms to thrombocytopenia, anemia, and acute graft dysfunction.³¹¹ Although all the patients eventually recovered, complications included bacterial superinfections, and one patient even required repeat liver transplantation from hepatic artery thrombosis and biliary stenosis 3 months after ZIKV infection.³¹¹

Neurologic Complications Including Guillain-Barré Syndrome

Early animal experiments of ZIKV in the 1950s discovered that ZIKV appeared to be neurotropic, a finding that has corresponded to more recent studies that have demonstrated ZIKV's ability to cause neuron cell death.^{51,89,109,237,245} Reported neurologic complications following acute ZIKV infection include encephalopathy, meningoencephalitis (including a case of fatal encephalitis secondary to severe cerebral edema),⁴¹⁹ seizures, acute sensory polyneuropathy, myelitis (including acute disseminated encephalomyelitis), and GBS.*

ZIKV and Guillain-Barré Syndrome

Although GBS may be a rare complication of other bacterial and viral infections, including other arboviral triggers such as Japanese encephalitis virus, West Nile virus, dengue virus, and chikungunya, considerable concern has been expressed over the increased incidence of GBS seen with or following ZIKV infection. GBS, a form of acute or subacute immune-mediated progressive flaccid paralysis, is considered a medical emergency requiring hospitalization and may also pose a risk for death.^{64,170,415,479} The scientific community has recently come to the consensus that ZIKV is, indeed, a cause of GBS.³³²

Early observations of the ZIKV epidemic in Brazil appeared to coincide with an increased incidence of GBS and other neurologic complications seen since May 2015, with some having estimated that the incidence of GBS increased fivefold since 2015.^{15,45,154} Approximately 49 cases of GBS in patients with a history of recent infection consistent with ZIKV were identified in Bahia, Brazil in July 2015.⁴⁶⁹ In Rio de Janeiro, Brazil, the RIO GBS-ZIKV Research Network reported that 17 of 20 patients with GBS seen from December 2015 to March 2016 were suspected to have had a ZIKV infection that preceded the development of GBS symptoms.¹⁴⁹ A study investigating temporal relationships between ZIKV and GBS in Salvador, one of the main epicenters of the ZIKV epidemic in Brazil, determined that the number of GBS cases peaked

*References 15, 17, 20, 45, 64, 67, 113, 114, 116, 136, 154, 218, 270, 272, 296, 308, 314, 349, 391, 392, 408, 414, 461, 480.

5 to 9 weeks after outbreaks of a new acute exanthematous illness were observed in Salvador, Brazil in 2015.³⁴⁷ The study provided additional support for an association between ZIKV and the development of complications such as GBS.³⁴⁷ Following these observations in Brazil, in June 2016, the WHO reported that 11 additional countries and territories (Colombia, Dominican Republic, El Salvador, French Guiana, Honduras, Martinique, Suriname, Venezuela, Haiti, Panama, Puerto Rico) demonstrated an increased incidence of GBS cases or reported cases of GBS in the context of ZIKV infection.^{218,339,391} Five GBS cases were also identified in returning US travelers with ZIKV infection.^{375,461} More recently, a multicountry review of GBS cases in Brazil, Colombia, Dominican Republic, El Salvador, Honduras, Suriname, and Venezuela has suggested a twofold to nearly 10-fold increase in GBS cases above baseline.¹¹⁶

GBS case series from French Polynesia, Brazil, Colombia, and Puerto Rico. Before the French Polynesia outbreak, ZIKV was largely believed to be a mild, febrile illness without serious complications.⁶⁴ However, during the 2013–14 outbreak in French Polynesia, significant rates of neurologic complications were observed, including GBS, that were not observed in earlier outbreaks such as the one on the Yap Islands.^{64,314} To date, the largest study documenting GBS after ZIKV infection was a case-control study during the French Polynesia outbreak, which included 42 GBS cases and provides the strongest evidence, thus far, that ZIKV is a cause of GBS (odds ratio [OR], >34).^{64,352} Of these patients, rapid deterioration was frequently noted, with 16 (38%) requiring intensive care admission and 12 (29%) requiring mechanical ventilation.^{250,323} Some have estimated that the incidence of GBS in French Polynesia was 0.24 to 0.41 per 1000 ZIKV infections, which would have constituted as high as a 21-fold increase in GBS incidence.^{64,479} Of note, none of the cases of GBS in the French Polynesia study were in children.¹⁵¹

Three additional case series of GBS patients from Colombia (two series) and Puerto Rico (one series) have also been reported. One included 68 patients with GBS, most of whom had the acute inflammatory demyelinating polyneuropathy GBS subtype. Almost all presented with limb weakness (97%), many reported paresthesias (76%) and facial palsy (32%), and about one-half (50%) had bilateral facial paralysis on examination.³⁴⁹ Nearly one-third (31%) required mechanical ventilation, and three patients died from respiratory failure and sepsis.³⁴⁹ Prolonged ZIKV viruria was also noted in patients with GBS and was reported in another case series.³⁹¹ Another case series of 19 patients with GBS from Colombia with a mean age of 44 years has also provided important information.¹⁷ The majority required respiratory ventilation (79%) and received intravenous immunoglobulin treatment (84%), with a few (16%) requiring plasmapheresis; severe disability (Hughes scale 4–5: chair-bound or bedridden and/or requiring ventilation assistance for at least part of the day) was noted in most (80%) on discharge.¹⁷ In both studies the mean time to development of GBS after ZIKV symptoms was 7 to 10 days.^{17,349} Both studies also found that the majority (80–82%) had albuminocytologic dissociation of the cerebrospinal fluid (CSF) (i.e., increased protein levels without pleocytosis).^{17,349} Another review of 56 patients with GBS from Puerto Rico, of whom 76% had confirmed or presumed ZIKV infection, reported that the majority had acute illness 5 days before development of GBS symptoms and 35% required ventilation (35%).¹¹³ All required hospitalization and were treated with standard GBS treatment of intravenous immunoglobulin G, but one patient died from complications of septic shock.¹¹³

ZIKV in Pregnancy and Congenital ZIKV Syndrome (Microcephaly and Other Congenital Complications)

Although it is believed that pregnant and nonpregnant women present similarly with acute ZIKV infection in terms of infectious symptoms, ZIKV infection in pregnancy presents unique challenges because it may have devastating consequences on the developing fetus.¹³³ In 2015, based on novel observations of infants exposed to ZIKV infection during pregnancy in Brazil, unprecedented global alarm was raised about the potential of ZIKV to cause congenital anomalies, including microcephaly.^{284,352,393,399} The PAHO subsequently issued alerts to its member states based on the troubling observations in Brazil. Additional evidence, including subsequent detection of ZIKV RNA from fetal brain and amniotic fluid specimens from fetuses and infants with microcephaly,

ultimately led to involvement of the European Centre for Disease Prevention and Control and the US CDC.⁴⁰⁶ By February 2016, the WHO declared ZIKV a “Public Health Emergency of International Concern.”^{467,406}

Since then, leaders at the WHO and CDC have come to the scientific consensus that ZIKV infection is a cause of microcephaly, and ZIKV is now considered to be the first major infectious disease associated with congenital birth defects to be discovered in more than half a century.^{73,322,332,352,385} As summarized in a special review published in the *New England Journal of Medicine* employing Shepard’s Criteria for Proof of Human Teratogenicity to ZIKV, the causal relationship between in utero ZIKV infection and microcephaly and other brain anomalies was substantiated by several factors: temporal relationship of ZIKV infection in pregnancy and anomalies observed; the otherwise rare phenotypic condition of microcephaly and other brain anomalies seen in fetuses and/or infants with congenital ZIKV infection; and detection of virus from brain tissue of ZIKV-infected fetuses and/or infants suggesting “biologic plausibility.”³⁸⁵ It has been suggested that ZIKV infection in pregnancy and sequelae may be due to direct infection of the trophoblast, viral invasion across the placenta, movement of infected cells leading to embryonic infection, or resulting effects of inflammatory cytokines released from infected placenta as well as ZIKV activation of neural cells’ TLR3 paths that then lead to neural cell death and thus fetal pathology seen in ZIKV-exposed infants.²²³

Per CDC definitions, congenital ZIKV is confirmed by a positive serum or urine ZIKV PCR collected ideally within the first 2 days of life.³⁹⁵ Whereas, a diagnosis of “probable congenital ZIKV infection” is based on a positive infant ZIKV immunoglobulin M (IgM) test with a negative ZIKV PCR.³⁹⁵ Although complete understanding of the complete spectrum of congenital anomalies that may be caused by ZIKV is still in evolution, reports of infants with congenital ZIKV have begun to describe a wide array of potential anomalies associated with in utero ZIKV infection. Lessons can be learned from other well-known viral congenital infections such as cytomegalovirus (CMV) and rubella, which have demonstrated the adverse effects these infections may have on the developing fetus, including the ability to affect hearing, vision, cognition, and motor development among others.^{88,223} It is believed that congenital ZIKV infection may also have the potential to cause widespread effects on the developing fetus with the most detrimental effects occurring during exposure in the first two trimesters of pregnancy.^{44,224,352}

Although early reports of ZIKV’s effects in pregnancy had primarily focused on microcephaly, later reports have described a host of other significant congenital anomalies; in fact, microcephaly appears to be just the tip of the iceberg.³¹⁷ In response to these observations of distinctive congenital anomalies observed in infants with in utero ZIKV exposure, the term *congenital Zika syndrome* was introduced. Based on preliminary studies, classic findings of congenital ZIKV syndrome now include fetal brain disruption sequence phenotype (severe microcephaly, craniofacial disproportion including collapse of skull and overriding cranial sutures, biparietal depression, prominent occiput, excess nuchal or scalp skin, and neurologic impairment), intracranial calcifications, eye abnormalities as well as sequelae of fetal akinesia deformation syndrome, including arthrogryposis (congenital contractures) and clubfoot.^{59,77,87,255,273,283,385,406} It is important to note that these brain anomalies may be observed in infants with or without microcephaly at birth. Many fetuses are also noted to have intrauterine growth restriction (IUGR).^{43,455} In addition, other adverse pregnancy outcomes, including miscarriage, stillbirth, and hydrops fetalis (with hydrothorax, ascites, and subcutaneous edema) have also been reported.^{44,255,256,404,444}

Specifically, the other congenital brain anomalies described with ZIKV include cerebral calcifications, gyral pattern anomalies, cerebellar and brainstem hypoplasia, absence of the corpus callosum, ventricular dilation, and hydranencephaly.* Reviews of literature and neuroimaging cases have suggested the most common brain abnormalities seen with congenital ZIKV syndrome apart from microcephaly include (1) diffuse intraparenchymal calcifications (often punctate, at the corticomedullary junction of the frontal/parietal lobes but may also be in the basal ganglia

*References 44, 90, 101, 104, 212, 238, 273, 284, 289, 317, 351, 352, 403, 448, 450, 466.

and cerebellum), (2) ventriculomegaly, and (3) cortical development malformations (abnormal gyration patterns).^{287,455,483}

These congenital neurologic abnormalities observed with in utero ZIKV infection, primarily characterized by severe fetal brain destruction, is most reminiscent of other congenital infections such as CMV, lymphocytic choriomeningitis virus, and toxoplasmosis, although to a lesser degree.⁴⁵⁵ Nevertheless, the presence of certain features of congenital ZIKV syndrome appear to help distinguish it from these other congenital infections.²⁸⁷ These findings include the severe microcephaly with partial skull collapse, the thin cerebral cortex with calcifications, dysgenesis of the corpus callosum, congenital contractures (including arthrogryposis along with early and severe hypertonia with extrapyramidal symptoms), macular scarring, and focal pigmentary retinal mottling.²⁸⁷

Arthrogryposis, which has been reported in 5.7% to 11% of congenital ZIKV cases, is thought to be due to the damage to upper and lower motor neurons.^{287,445} It may involve upper or lower limbs (proximal or distal) and may vary in severity.^{287,445} In extreme cases, bilateral congenital hip dislocation and even partial or full knee dislocation have been reported.^{287,445} Apart from arthrogryposis, other findings of fetal akinesia disruption sequence include isolated clubfoot, which has been seen in 3.8% to 14% of cases of congenital ZIKV.²⁸⁷ Other neurologic problems observed in these infants include seizures, tremors, posturing, hypertonia with spasticity, severe irritability, and dysphagia.^{43,287,446}

Sensorineural hearing loss (in 6% of cases of congenital ZIKV infants with microcephaly), including severe bilateral hearing loss, has also been described.^{238,239} In addition, ocular abnormalities in infants with congenital ZIKV also appear to be common, ranging from 35% to 46% of infants with microcephaly and intracerebral calcifications to as many as 100% of these infants in some small case series.^{104,443,448,449} One study suggested that infants with ocular findings were more likely to have smaller cephalic perimeters and have been born to women who had ZIKV symptoms during the first trimester of pregnancy.⁴⁴⁹ ZIKV ocular abnormalities described include focal retinal pigment mottling, chorioretinal atrophy, optic nerve changes, lens subluxation, loss of foveal reflex, iris colobomas, microphthalmia, cataracts, intraocular calcifications, and myopia, among others.^{104,282,287,443,448–450} Interestingly enough, active chorioretinitis, a classic finding in congenital infections, has not yet been reported with congenital ZIKV, and pathology of the posterior eye has been more commonly seen.²⁸⁷

Microcephaly and Other Congenital Cerebral Abnormalities

Although ZIKV is now considered to be a cause of microcephaly, the condition itself can be due to a variety of etiologies, including other

congenital infections (rubella, toxoplasmosis, CMV), severe malnutrition, fetal ischemia during development, chromosomal changes, craniosynostosis, metabolic disorders, and in utero exposure to drugs, alcohol, and other environmental toxins.^{84,367,386,406,454} Historically, in the general population microcephaly is considered a rare clinical finding; it is characterized by a small head and typically reflects brain growth disturbances during development that often lead to developmental delay, vision and hearing impairment, and other neurologic problems such as seizures. Specifically, it is believed that disruption to the fetal brain growth sequence can lead to fetal skull collapse, which ultimately can give rise to microcephaly.³⁵² Microcephaly prevalence was previously reported to be 0.5 to 2 per 10,000 live births in Brazil and 1.9 to 2 per 10,000 live births in the United States and Europe.^{57,68,129,352,367,420} (See Figs. 176H.8 and 176H.9E for depictions of microcephaly.)

The definitions of microcephaly have varied by country and have been one challenging aspect impeding accurate monitoring of microcephaly incidence in the setting of ZIKV.²¹⁷ Some have defined microcephaly as head circumference (occipitofrontal) less than the 3rd percentile or less than 2 standard deviations (SD) for gestational age and sex, with severe microcephaly being defined as less than 3 SD for gestational age and sex.^{217,352,452} The working microcephaly case definition used by the CDC is head circumference less than the 3rd percentile adjusted for gestational age and sex.^{71,151,354,363} (In Brazil, since December 2015, the Ministry of Health has been using a case definition of microcephaly as a head circumference ≤ 32 cm in any full-term newborn or <2 SD for gestational age and sex for premature infants in their surveillance, but had previously used the definition of ≥ 3 SD below the mean for gestational age and sex, which is more restrictive and would correspond to 30.3 cm for females and 30.7 cm for males; this was followed by a temporary change in ad hoc surveillance definitions in November 2015 to ≤ 33 cm before the new case definition was being used.^{224,452})

Another important consideration regarding the characterization of microcephaly is whether it is proportional or disproportional. It should be noted that microcephaly is generally a postnatal diagnosis that cannot be clearly ascertained by fetal ultrasound. IUGR will render an infant who is universally small for gestational age (SGA), a finding that has been reported in ZIKV congenital infection.^{43,44,455} For gestational age, these SGA infants may be considered microcephalic; however, microcephaly in this instance would be proportional to the infant's overall size. In contrast, most reports of microcephaly in ZIKV-infected infants describe disproportionate microcephaly, in which the head circumference

FIGURE 176H.8 Depiction of measurements of typical infant head size, microcephaly, and severe microcephaly. (From Centers for Disease Control and Prevention. Zika virus: information for clinicians. June 13, 2016. <https://www.cdc.gov/zika/hc-providers/qa-pediatrician.html>.)

FIGURE 176H.9 Neuroimaging and sequelae seen in congenital Zika virus syndrome. (A–D) Magnetic resonance images of cranial-facial disproportion with microcephaly. Diffuse reduction in white-matter thickness with corpus callosum was not identified. Diffuse pachygyria is more evident in the right parietal lobe. Also seen are supratentorial ventricular dilatation, atrophy of the cerebellar vermis with ample communication of the fourth ventricle with the cisterna magna, and widening of the perivascular spaces of the cerebellar hemispheres with surrounding gliosis. (E–J) Clinical features of Zika virus infection in infants. (E) Disproportionate microcephaly. (F) Arthrogryposis at birth. (G) Redundant scalp. (H) Cortical thumb. (I) Knee fovea. (J) Left infant retina demonstrating optic disc hypoplasia, peripapillary atrophy, and macular chorioretinal atrophy with a colobomatous-like aspect with hyperpigmented halo and pigmentary mottling. (From Brasil P, Pereira JP Jr, Moreira ME, et al. Zika virus infection in pregnant women in Rio de Janeiro. *N Engl J Med*. 2016;375[24]:2321-2334.)

does not correspond to other anthropometric measures, including weight and length.¹⁶⁵

ZIKV Cases in Pregnant Women in Brazil, French Polynesia, Other Latin American Countries, and the United States

ZIKV cases in pregnant women in Brazil. After recognition of clusters of a febrile rash illness observed in Northeastern Brazil since late 2014,

which was later attributed to ZIKV transmission, with confirmed subsequent transmission in all five regions of the country, a substantial increase in cases of microcephaly was reported to the Ministry of Health in Brazil in October 2015.²²⁴ By January 2016, a total of 3530 suspected microcephaly cases had been reported, which was a significant increase over the 0.5 to 0.6 cases per 10,000 live births previously reported.^{224,406}

A Brazilian Zika Embryopathy Task Force was then established to review

cases of microcephaly born to mothers with suspected ZIKV infection during pregnancy.⁴⁰⁶ One study analyzing data on microcephaly and ZIKV-infected pregnant women from the Bahia state in northeast Brazil has estimated that the risk for microcephaly following ZIKV infection during pregnancy ranges from 0.88% to 13.2%.^{211,263}

Because the majority of cases of global ZIKV-associated microcephaly have occurred in Brazil, many of the early reports from Brazil were critical in supplying evidence linking ZIKV infection with microcephaly and other cerebral anomalies (see Table 176H.1). Reports from Brazil also continue to provide important information that has helped define the range of sequelae resulting from the congenital ZIKV epidemic. One of the two major epidemiologic studies providing evidence for a causal relationship between ZIKV and congenital anomalies such as microcephaly and other cerebral anomalies seen on fetal ultrasound was a preliminary report of 72 pregnant women in Rio de Janeiro enrolled with PCR-confirmed ZIKV from September 2015 to February 2016 at various gestational ages (5–38 weeks).⁴⁴ Although clinical infection in these women was mild, fetal anomalies were detected by ultrasound in 29% of them.⁴⁴ Fetal abnormalities, including early and late fetal death, IUGR with and without microcephaly, CNS lesions, abnormal amniotic fluid, and cerebral and umbilical artery flow anomalies were observed⁴⁴ (Table 176H.5). A subsequent report of the same prospective cohort revealed that in 125 ZIKV-affected pregnancies, overall adverse outcomes occurred in 46%, including fetal death in 7% of pregnancies. In addition, among 117 live infants born to PCR-proven ZIKV-infected women, 42% of infants had abnormal clinical or neuroimaging, with adverse outcomes noted regardless of the trimester of maternal infection.⁴³

Early Brazilian case reports also contributed to the accumulating evidence linking ZIKV infection in pregnancy and congenital sequelae

such as microcephaly. One was a case study of two pregnant women with fetal microcephaly and clinical manifestations of acute ZIKV infection (fever, myalgia, and rash).⁵⁹ ZIKV was recovered from the amniotic fluid in both women, and the full ZIKV genome was sequenced from one of them.⁵⁹ The study demonstrated that ZIKV had the capability to breach placental barriers, and sequencing of the virus' genome revealed that the ZIKV strain circulating in Brazil likely originated from the outbreak in French Polynesia.⁵⁹ Similarly, another case report detailed the evaluation of brain and placental tissue from two miscarriages and two newborns born to mothers from Rio Grande do Norte with symptomatic ZIKV infection in pregnancy.²⁵⁶ Histopathologic changes in the neonates' brains showed parenchymal calcification, microglial nodules, gliosis, cell degeneration, and necrosis but did not show other organ tissue abnormalities.²⁵⁶ Placental tissue from one of the miscarriages showed heterogeneous chorionic villi with calcification, fibrosis, perivillous fibrin deposition, and patchy intervillitis and focal villitis.²⁵⁶ The ZIKV RT-PCR assay was also positive, and the complete ZIKV genome was again recovered.²⁵⁶ In addition, compatible findings with ZIKV infection were also noted on autopsy of a fetus of a European woman with a history of suspected ZIKV infection while living in Brazil during the end of her first trimester.²⁸⁴ The fetus had microcephaly, agyria, hydrocephalus, and calcifications of the brain and placenta.²⁸⁴ Electron microscopy of fetal brain tissue appeared to demonstrate viral replication in the brain.²⁸⁴ Investigators noted that ZIKV also appeared to be able to damage the placenta based on placental pathology, but ZIKV was not detected in other fetal organs apart from the brain, which reinforced findings of other studies suggesting ZIKV's neurotropism.²⁸⁴

Preliminary results from the first case-control study of microcephaly and congenital ZIKV from Recife, one of the epicenters of microcephaly

TABLE 176H.5 Preliminary Prenatal Ultrasound Findings From Pregnant Women With Zika Virus Infection in Rio de Janeiro, Brazil

No. of Fetuses	Week of Gestation at Infection	Week of Gestation at Ultrasound Examination	Abnormal Findings on Doppler Ultrasonography	Findings at Birth
19	8	35	Microcephaly, cerebral calcifications, abnormal middle cerebral artery, intrauterine growth restriction	Microcephaly, cerebral calcifications on CT, global cerebral atrophy, macular lesions
40	8	20	Choroid plexus cyst, cerebellar atrophy (transverse diameter <5th percentile)	Still in utero
24	12	29	Microcephaly, cerebral calcification, Blake's cyst, agenesis vermis, club foot, intrauterine growth restriction	Still in utero
41	12	24	Mega cisterna magna (>95th percentile)	Still in utero
39	21	30	Cerebellar and cerebral right periventricular calcifications	Still in utero
17	22	26	Middle cerebral artery flow <5th percentile	Still in utero
12	22	27	Microcephaly, placental insufficiency as assessed by Doppler study, oligohydramnios, intrauterine growth restriction	Small for gestational age, head circumference proportional to body size, macular lesions
10	25	30	Normal first ultrasonogram, fetal death detected at 36 weeks on repeat ultrasonogram	Stillbirth
36	26	35	Microcephaly, abnormal umbilical artery flow (>95th percentile on the pulsatile index), intrauterine growth restriction	Small for gestational age, head circumference proportional to body size
38	27	35	Cerebral calcifications, ventriculomegaly, brachycephaly	Still in utero
2	30	34	None	Normal at birth
3	31	33	None	Normal at birth
53	32	38	Fetal death	Stillbirth
23	35	40	Anhydramnios, intrauterine growth restriction	Normal growth measure, poor sucking reflex, EEG abnormalities

CT, Computed tomography; EEG, electroencephalogram.

From Brasil P, Pereira JP Jr, Raja Gabaglia C, et al. Zika virus infection in pregnant women in Rio de Janeiro: preliminary report. *N Engl J Med*. 2016;375(24):2321-2334.

cases in Brazil, also reported a strong association between congenital ZIKV and microcephaly (OR, 55.5; 95% CI, 8.6–∞), which was even higher for those cases of microcephaly with other brain abnormalities identified by imaging (OR, 113.3; 95% CI, 14.5–∞); 41% of microcephaly cases and none of controls had laboratory-confirmed ZIKV.^{42,99} Although these preliminary results from the 32 infant cases with microcephaly and 62 controls provide additional evidence supporting ZIKV as a cause of microcephaly, the results of the complete study (200 cases and 400 controls anticipated) will be reported when available.²⁶¹

Other studies from the Bahia State have also found ecologic evidence of a temporal relationship between maternal ZIKV infection during pregnancy and microcephaly.^{347,387} In 2015, it was noted that suspected cases of microcephaly in Salvador, Brazil peaked 30 to 33 weeks after the emergence of acute exanthematous illness outbreaks.³⁴⁷ Similar conclusions were drawn from another study of 574 microcephaly cases in Brazil that established both temporal and geospatial evidence linking ZIKV disease in the first trimester of pregnancy with increased prevalence of microcephaly.²²⁴ However, findings of one study and a case report have suggested that even ZIKV infection in the third trimester of pregnancy may lead to serious neurologic damage in the developing fetus.^{43,421}

The studies from Brazil on microcephaly, congenital brain anomalies, and ZIKV have demonstrated that our knowledge about ZIKV congenital syndrome is quickly evolving. Of the 20 Brazilian states reporting cases of microcephaly, the state of Pernambuco initially reported the most, with 874 reported cases.^{277,406} A preliminary analysis of 104 microcephaly cases (defined as head circumference <3% for gestational age and sex) in Pernambuco was conducted by the CDC and published in June 2016 and demonstrates the frequency and extent of neurologic damage seen in congenital ZIKV cases.²⁷⁷ Approximately 67% of these infants had severe microcephaly with a head circumference of <30 cm³. Of the 58 infants who underwent radiographic imaging, nearly all (93%) had calcifications, which were primarily localized to the cortical and subcortical junctions, although some were also seen in the periventricular region, basal ganglia, thalamus, midbrain, and cerebellum.²⁷⁶ Many infants (69%) also had cortical development malformations, including neuronal cell migration abnormalities such as lissencephaly (“smooth brain”), pachygyria (malformed cortical folds with “thick gyri”), and agyria (lack of cortical folds).²⁷⁶ Many infants (66%) also had ventriculomegaly due to cortical or subcortical atrophy.²⁷⁶ Similar findings were seen in other, smaller series of infants with congenital ZIKV infection, in whom calcifications, cortical development malformations, decreased brain volume, ventriculomegaly, and hypoplasia of the brainstem or cerebellum were extremely common.^{101,293,406} Redundant scalp skin and arthrogryposis resulting from central and peripheral nervous system damage following in utero cerebral growth arrest were also common findings, and some had detectable IgM antibodies to ZIKV in their CSF^{101,406} (see Fig. 176H.9).

Yet, it may be also important to keep in mind that although microcephaly is one potential marker of the ZIKV congenital syndrome, focusing on microcephaly alone may underestimate the true magnitude of this major epidemic.¹⁵⁷ This idea is underscored by recent findings of a report evaluating 13 Brazilian infants from the states of Pernambuco and Ceará with prenatal ZIKV exposure who developed microcephaly after birth.⁴⁴⁶ At birth these infants were not microcephalic, but they had abnormal findings on neuroimaging, with nearly all having decreased brain volume (92%), ventriculomegaly (85%), calcifications (100%), or cortical malformations (100%).⁴⁴⁶ In addition, all infants had decreases in their rate of head circumference growth after birth, and 11 of 13 (85%) were ultimately given a diagnosis of postnatal or secondary microcephaly.⁴⁴⁶ Other common findings included hypertonia (100%), pyramidal and extrapyramidal signs (92%), dysphagia (77%), no voluntary hand movement (69%), epilepsy (54%), irritability (39%), arthrogryposis or hip dysplasia (23%), and chorioretinal abnormalities of the eye (23%).⁴⁴⁶

Although long-term outcomes of infants with congenital ZIKV syndrome are still under investigation, one study of 48 Brazilian infants with probable congenital ZIKV syndrome (all with abnormal neuroimaging) evaluated over the first 1 to 8 months of life has provided some early insight into some of their long-term health issues.²⁹³ Common chronic issues included irritability (85%); pyramidal/extrapyramidal

syndrome (56%), including hypertonia, clonus, and hyperreflexia; epileptic seizures (50%); dysphagia (15%); and orthopedic morbidities associated with congenital clubfoot (10%) and arthrogryposis (10%).²⁹³ Similar to the previously mentioned study, three infants with abnormal neuroimaging but without microcephaly at birth were later noted to have microcephaly postnatally, which underscores the importance of close monitoring of postnatal growth parameters, particularly head circumference.²⁹³

Reports from the Brazilian Ministry of Health at the end of July 2016 have also begun to question whether other factors apart from ZIKV may have contributed to the number of ZIKV-related microcephaly cases in Brazil because the majority of cases of microcephaly (90%) were from only a small region of the country (Northeast Brazil) and primarily were among poor, young, single, black pregnant women. These findings have prompted questions about the possibility of other biologic and socioeconomic factors, including coinfections with dengue and chikungunya, low yellow fever vaccination rates, and even the bovine viral diarrhea virus, of which proteins have been recovered from three fetuses with microcephaly.⁵⁶ Another hypothesis for contributing factors for the microcephaly epidemic, particularly in Northeast Brazil, focused on the use of the larvicide pyriproxyfen in potable water tanks, but ecological studies have not supported any association.¹¹ Thus far, no contributing factors to the ZIKV-associated microcephaly and congenital cerebral anomalies epidemic in Brazil have been identified. An alternative explanation is that ZIKV attack rate in Northeastern Brazil was exceedingly high, with most of the population becoming infected.

ZIKV cases in pregnant women in French Polynesia. After the announcement of observations of congenital anomalies such as microcephaly observed in Brazil during the 2015 ZIKV outbreak, researchers recently retrospectively reviewed 19 cases of infants with congenital cerebral malformations and dysfunction born from pregnancies during the 2013–14 French Polynesia ZIKV epidemic.³² From 2014 to 2015, in the year following the French Polynesia ZIKV epidemic, an increase in congenital brain malformations was observed there, which included cerebral malformations (2-fold), brainstem dysfunction (31-fold), and severe microcephaly (14-fold) increases in fetuses and newborn infants.³² Cerebral lesions included septal and callosal disruption, ventriculomegaly, abnormal neuronal migration, cerebellar hypoplasia, occipital pseudocysts, and brain calcifications.³² ZIKV RNA was also isolated retrospectively from amniotic fluid in four of seven cases with severe neurologic impairment, demonstrating in utero ZIKV infection.³²

An additional retrospective modeling study of microcephaly cases from 2013 to 2015 in French Polynesia by the same group of researchers suggested that the cluster of cases of microcephaly could best be explained by ZIKV infection in the first trimester of pregnancy, and the risk for microcephaly was 95 cases (95% CI, 34–191) per 10,000 pregnant women infected in the first trimester (or 0.95%),²¹¹ which greatly exceeded the baseline microcephaly prevalence of 2 cases (95% CI, 0–8) per 10,000 neonates in that region.⁶⁸

ZIKV cases in pregnant women in Colombia and other Latin American countries. After recognition of the Brazilian ZIKV outbreak, monitoring quickly became established in other Latin American countries, including Colombia in August 2015, where the first laboratory-confirmed cases of ZIKV were reported in October 2015. Initially, there were 50 reported cases of microcephaly, of which 20 were determined to be due to causes other than ZIKV.³⁴³ As of December 29, 2016, there have been approximately 72 infants born with congenital ZIKV syndrome in Colombia.^{335,338,343} In addition, early findings from some of the studies in Brazil,⁴⁴ as well as from French Polynesia,⁶⁹ have also prompted hypotheses, including whether symptomatic ZIKV infection may be a predictor of ZIKV complications such as fetal abnormalities in pregnant women.^{70,159} However, four cases of infants in Colombia with congenital ZIKV were born to women with asymptomatic ZIKV infection in pregnancy, and additional analyses evaluating the severity of ZIKV infection in pregnancy with infant outcomes have failed to substantiate those earlier hypotheses.^{265,343}

Two case reports of pregnant European women traveling to Latin American countries have provided additional insight into the timing and pathogenesis of ZIKV-induced complications in pregnancy. One case was a woman traveling to several Latin American countries (Mexico,

Guatemala, and Belize) during 11 weeks' gestation, who became symptomatic after contracting ZIKV infection.¹¹⁹ Seven weeks after resolution of her symptoms, her sequential fetal ultrasounds at 19 and 20 weeks showed fetal intracranial anomalies with diffuse cerebral cortical thinning and significant decrease in head circumference.¹¹⁹ Maternal viremia (ZIKV RNA RT-PCR) was still detected at 4 and 10 weeks after clinical ZIKV infection, which was hypothesized to be due to high levels of fetal or placental viral replication.¹¹⁹ Postmortem fetal autopsy revealed high ZIKV loads from fetal brain, membranes, umbilical cord, and placenta; histopathology demonstrated significant apoptosis of intermediately differentiated postmigratory neurons and isolation of ZIKV from fetal brain tissue.¹¹⁹ The other case was a woman visiting Suriname at 6 to 7 weeks' gestation whose pregnancy was complicated by ZIKV infection and miscarriage at 11 weeks' gestation.⁴⁴⁴ Histopathologic analysis determined evidence of ZIKV infecting amniotic epithelial and fetal mesenchymal cells, particularly the perichondrium.⁴⁴⁴ These findings suggested ZIKV replication in pluripotent amniotic stem cells, which are critical in early embryonic development.⁴⁴⁴

ZIKV Cases in Pregnant Women in the United States and US Territories

A summary report released by the CDC noted that by March 2016, 3335 pregnant women in the United States had received ZIKV testing, with only 28 (0.8%) having confirmed ZIKV infection.⁹⁷ Overall, the percentage of symptom-free pregnant women tested for ZIKV, who had the infection, was very low (0.3%).⁹⁷ In fact, more than 99% of these symptom-free pregnant women tested for ZIKV did not have the infection, whereas 64% of pregnant women with confirmed ZIKV had at least one of the typical ZIKV-associated symptoms.⁹⁷ Current aggregate data from the CDC's US Zika Pregnancy Registry, updated on December 13, 2016, revealed that there are more than 1246 pregnant women with laboratory evidence of possible ZIKV infection and another 2701 women in the US Territories (American Samoa, Puerto Rico, and the US Virgin Islands).³⁷¹ Of these women with outcomes available in the United States as of December 29, 2016, there have been 39 cases of congenital ZIKV syndrome.³⁷⁰ Some have estimated that as many as 100 to 270 cases of congenital microcephaly from ZIKV will follow the epidemic in Puerto Rico.¹³² A preliminary report of 442 completed pregnancies found that ZIKV-related birth defects were observed in 6% of pregnancies, with no difference for pregnant women with symptomatic versus asymptomatic infection.¹⁹⁸ ZIKV-related birth defects were as high as 11% when ZIKV infection occurred in the first trimester, and the rate of microcephaly for completed pregnancies was 4% (18 cases).¹⁹⁸ (Refer to the CDC webpage for the most recent released data at <http://www.cdc.gov/zika/geo/pregwomen-uscases.html>.)

The full extent of problems that ZIKV may cause in pregnancy is an evolving story and currently under intense investigation by researchers around the world. At the present time, there is no evidence that prior infection with ZIKV will negatively affect future pregnancies.³⁶³ However, the true impact of ZIKV infection in women of childbearing age and the degree of chronic morbidities faced by infants with congenital ZIKV infection remain to be seen.

ZIKV DIAGNOSIS, MANAGEMENT, TREATMENT, AND PREVENTION

ZIKV Diagnostics

Accurate diagnosis of acute ZIKV infection is difficult to make based on clinical presentation because of significant overlap in symptoms of ZIKV with dengue virus and chikungunya as well as a broad differential of other infections with a rash that may be considered. Infections in the differential diagnosis of ZIKV include other flavivirus infections (dengue, West Nile virus, yellow fever), malaria, leptospirosis, rickettsia, other alpha viruses (chikungunya, Mayaro, Ross River, Barmah Forest, O'nyong-nyong, and Sindbis viruses), other viral illnesses associated with exanthems such as parvovirus B19, enterovirus, rubella, measles, adenovirus, herpesviruses (CMV, Epstein-Barr virus, human herpesvirus type 6), and acute HIV infection.^{346,364,460}

Historical Methods for ZIKV Evaluation

Historically, viral cultures have been used for ZIKV research, but these are not available for routine clinical use.⁴⁶⁰ ZIKV can be cultured in several cell lines, including African green monkey (Vero), rhesus monkey kidney (LL-MK2), *Aedes pseudoscutellaris* (MOS61 or AP61), and *Aedes albopictus* (C6/36).⁴⁶⁰ (See also earlier section on **Viral Pathogenesis**.) In early animal studies, for successful isolation of the virus, intracerebral mouse inoculation was required.^{111,112,182,232,460} Early studies of ZIKV infection in humans were based on seroepidemiologic studies of ZIKV neutralizing antibodies detected in serum, which even then observed some cross-reactivity of ZIKV antibodies with those of dengue and yellow fever virus.* Since 2008, RT-PCR has been used to detect ZIKV RNA in a variety of specimens, including serum, plasma, urine, saliva, amniotic fluid, breast milk, and tissues.^{25,143,458,460} Recently, whole blood was also included as a specimen option for RT-PCR per CDC guidelines.¹⁴ Specific ZIKV RT-PCR assays that were used from 2008 to 2014, including the type of RT-PCR, source, primer/probe, sequence, and position, are available in the literature.⁴⁶⁰

Current Methods for ZIKV Evaluation

At present, the primary methods available for diagnostic testing of ZIKV include RT-PCR, serology (IgM) including neutralizing antibodies by plaque reduction neutralization test (PRNT), and immunohistochemical staining.^{362,363} In the United States, testing is primarily done at the CDC. Some state health departments and commercial laboratories have efforts underway to expand diagnostic capabilities in several states. It is recommended that clinicians contact their state health departments to facilitate any ZIKV diagnostic testing.^{362,363}

Acute Phase ZIKV Testing Using RT-PCR-Based Methods

During the acute phase of the illness, ZIKV RT-PCR may be used to detect virus RNA from clinical specimens, depending on the time of presentation after the onset of clinical symptoms.^{205,362} It was previously recommended that ZIKV RT-PCR from serum only be used early in the illness (<7 days after clinical illness onset), whereas urine (<14 days after illness onset) may be used for a longer period after the onset of symptoms.^{205,363} However, based on newer CDC guidelines from November 2016, it is now recommended that *both* serum and urine be collected from all patients with symptoms who present less than 14 days after onset of their symptoms in order to test using ZIKV RNA RT-PCR.⁷² Whole blood may also be collected along with serum because ZIKV RNA may be detected for longer periods in whole blood than in serum.⁷² If these ZIKV RT-PCR results are negative, then serology (serum ZIKV IgM testing) should be done as well as testing for dengue, particularly if there are exposures or if the patient is pregnant.⁷² (See more information later regarding ZIKV serology considerations) (Fig. 176H.10).

Of note, a recent study conducted by the Florida Department of Health in 70 patients with suspected ZIKV disease highlights the differences in diagnostic yield using ZIKV RT-PCR on different bodily fluid specimens.³⁵ In this study, 95% of urine specimens collected within 5 days of symptom onset tested positive for ZIKV RNA RT-PCR, as opposed to only 56% of serum specimens.³⁵ The study also demonstrated that ZIKV RNA detection in saliva within the first 5 days of symptoms was better than that in serum, with the percentage of detection in saliva approaching that of urine specimens.³⁵ However, despite this study's findings, it should be noted that because of issues with processing saliva samples for ZIKV RT-PCR, saliva is not currently recommended as part of routine specimen collection in the evaluation of ZIKV infection.²³⁴

Note that various NAATs have been approved by the FDA through Emergency Use Authorization (EAU), and a list of all of these ZIKV EUAs are available on the FDA website (<http://www.fda.gov/MedicalDevices/Safety/EmergencySituations/ucm161496.htm>).^{72,234} Apart from CDC Triplex RT-PCR, this includes other tests by Focus Diagnostics, Altona Diagnostics, Hologic, Viracor-IBT, Siemens Healthcare Diagnostics, Luminex, and Roche Molecular Systems.²³⁴

*References 7, 111, 137, 181, 188, 248, 319, 358, 416–418, 460.

Beyond the Period of ZIKV Acute-Phase Testing (Serology and PRNT Testing)

Beyond the acute phase of the illness after 2 weeks (≥ 14 days), it is recommended that serology for ZIKV IgM (typically the IgM antibody capture enzyme-linked immunosorbent assay [MAC-ELISA]) from collected serum be used to diagnose infection up to 12 weeks after illness onset.^{72,205,363} This also includes the use of the PRNT to evaluate for virus-specific neutralizing antibodies in paired serum samples for any test result on MAC-ELISA indicating anti-ZIKV IgM antibodies (which includes a positive, equivocal, or presumptive/possible ZIKV-positive result)^{72,205,363} (Fig. 176H.11).

Anti-ZIKV IgM antibodies will be detectable in serum within the first week after symptom onset (possibly as early as 4–5 days) and be present for 8 to 12 weeks after.^{72,384} It should also be noted that in some patients RT-PCR testing may be positive (particularly for urine and whole blood) for longer than 2 weeks after onset of ZIKV symptoms.⁷² Thus it may be of benefit to send serum as well as whole blood and urine for ZIKV RNA NAATs even beyond the acute phase of illness of 2 weeks.⁷²

Note that testing recommendations for pregnant women are somewhat different and include testing using ZIKV RT-PCR on all available specimens (serum, urine, whole blood), even if presenting more than 2 weeks beyond symptom onset, as well as dengue IgM testing.⁷² For symptom-free pregnant women, repeat testing should be done 2 to 12 weeks after exposure, even if the first test results were negative.⁷²

Because ZIKV serology (IgM) may cross-react with antibodies to other flavivirus infections such as dengue and yellow fever viruses, neutralizing antibody testing (PRNT) can be used to help differentiate between these cross-reacting antibodies that may occur in patients with primary flavivirus infections and those occurring in previously infected patients or patients vaccinated against flaviviruses.³⁶³ PRNT evaluates

for neutralizing antibodies to ZIKV as well as other flaviviruses that can cross-react with ZIKV serology.⁷² For instance, cases of acute ZIKV infection in travelers returning from the Pacific Islands and Southeast Asia have been reported to have false-positive testing results for dengue virus IgM.^{152,232,410,425,433,481} (Box 176H.1). In the United States, PRNT is typically done either at the CDC or at another CDC-qualified laboratory.⁷² However, the use of PRNT for ZIKV and dengue in Puerto Rico is an exception to these CDC guidelines and is not routinely recommended given high rates of cross-reactivity.⁷²

Guidelines from the CDC and from local and state health departments can assist providers in interpreting serology results.³⁸⁴ Further details regarding interpretation of ZIKV testing results and ZIKV laboratory testing protocols are available on the CDC website (<http://www.cdc.gov/zika/state-labs/index.html>) and in Box 176H.1.

It should also be noted that both MAC-ELISA and PRNT are labor-intensive methods for ZIKV infection diagnosis, and there is a great need for the development of more specific, user-friendly, rapid ZIKV diagnostic tests.²³⁴ A potential future diagnostic method is the ultrasensitive electrogenerated chemiluminescence-based immunoassay for ZIKV detection in bodily fluids.⁴

Other Specimen-Testing Methods

ZIKV testing can also be done on other bodily fluids, although these are not considered primary diagnostic specimens. Cerebral CSF can be tested using ZIKV RNA RT-PCR and ZIKV IgM.⁷² Amniotic fluid may also be tested for ZIKV RNA using RT-PCR.⁷² At present, there are no FDA-authorized tests that accept use of saliva or semen for ZIKV testing.⁷²

In addition, if tissue samples are available for testing, immunohistochemical staining can be done to look for ZIKV antigens, and RT-PCR can also be done on fixed tissues.³⁶³ Of note, ZIKV testing that can be used in formalin-fixed, paraffin-embedded (FFPE) tissue samples has

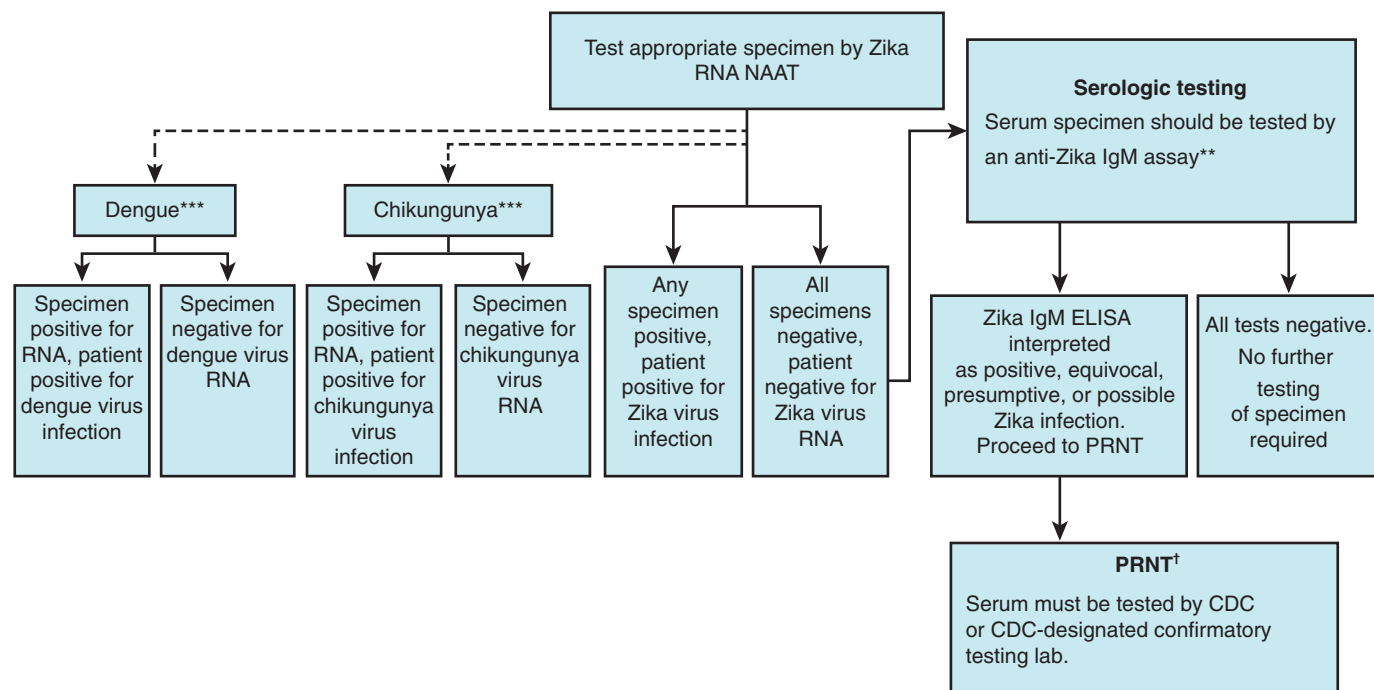

FIGURE 176H.10 Algorithm created by the Centers for Disease Control and Prevention (CDC) to help guide testing of individuals in the United States with symptomatic acute Zika virus infection. Specimens are collected <14 days after symptom onset. All test results should be reported. Results should be considered in the context of symptoms, exposure risk, and time point of specimen collection. *Pregnant and nonpregnant symptomatic individuals. **Note that antibody cross-reactivity to other flaviviruses (e.g., dengue) complicates interpretation of the current anti-Zika immunoglobulin M (IgM) tests. Dengue IgM testing should be conducted for symptomatic pregnant women, for individuals with a potential dengue exposure, and when a presumptive other flavivirus result is obtained. ***Testing and interpretation for the CDC Triplex assay. Note that when testing urine and amniotic fluid with the CDC Triplex assay, only report the Zika result. †Plaque reduction neutralization test (PRNT) confirmation is not currently routinely recommended in Puerto Rico. NAAT, nucleic acid amplification testing. (From Centers for Disease Control and Prevention. Guidance for U.S. laboratories testing for Zika virus infection. November 16, 2016. <https://www.cdc.gov/zika/images/laboratories/zikaalgorithm-1.jpg>. <https://www.cdc.gov/zika/hc-providers/testing-guidance.html>.)

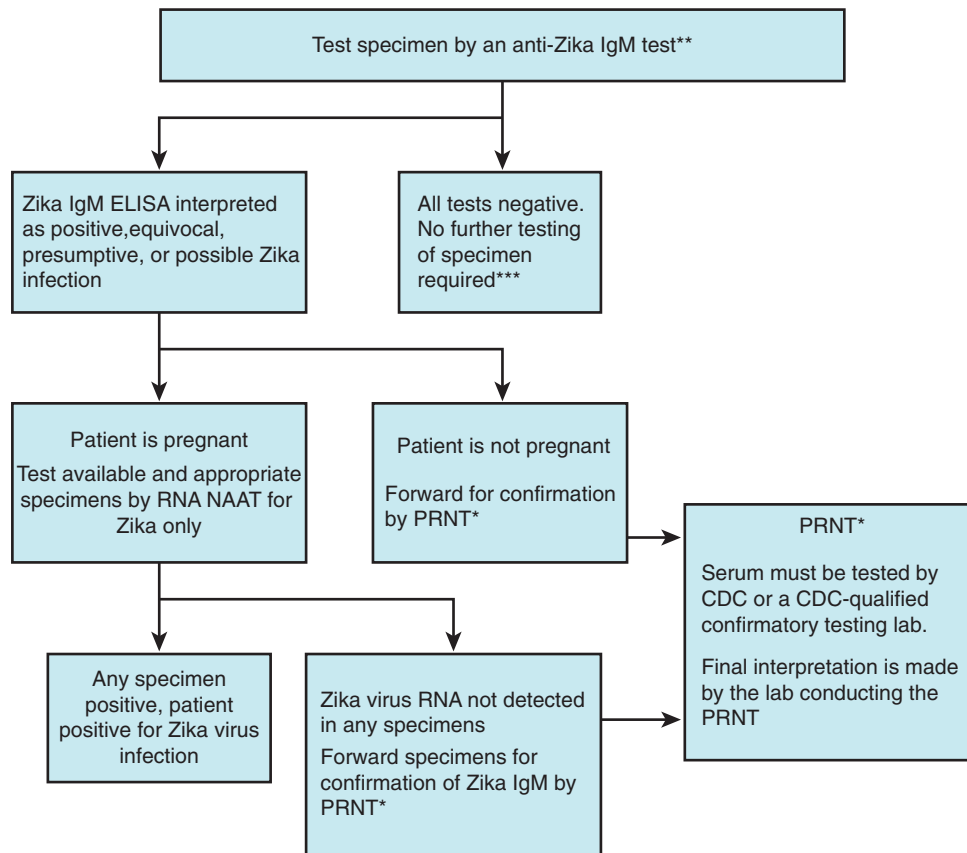

Figure 176H.11 Algorithm from the Centers for Disease Control and Prevention (CDC) for testing of symptomatic individuals in the United States for Zika virus beyond the acute period of infection. Specimens are collected ≥ 14 days after symptom onset. All test results should be reported to the appropriate health authorities. Results should be considered in the context of symptoms, exposure risk, and time point of specimen collection. *Plaque reduction neutralization test (PRNT) confirmation is not currently routinely recommended for Puerto Rico. **Note that antibody cross-reactivity to other flaviviruses complicates interpretation of the current anti-Zika immunoglobulin M (IgM) tests. Dengue IgM testing should be conducted for symptomatic pregnant women, for individuals with a potential dengue exposure, and when a presumptive other flavivirus result is obtained. ***Note that if tests for Zika and dengue IgM are not reactive, anti-chikungunya IgM testing should be performed for persons with chikungunya exposure risk and a clinically compatible illness. ELISA, enzyme-linked immunosorbent assay; NAAT, nucleic acid amplification testing. (From Centers for Disease Control and Prevention. Guidance for U.S. laboratories testing for Zika virus infection. November 16, 2016. <https://www.cdc.gov/zika/laboratories/lab-guidance.html>.)

been under development at the CDC since November 2015. The FFPE tissue testing methods include ZIKV RT-PCR that targets the virus NS5 and envelope genes and immunohistochemistry testing that employs a mouse polyclonal anti-ZIKV antibody.^{256,460}

New ZIKV diagnostic testing developments. According to the WHO, more than 55 new ZIKV diagnostic tests have been developed in response to the great need for better ZIKV diagnostics.⁴⁶⁹ In addition, the FDA approved EUA for several ZIKV diagnostic kits. One of the most popular tests is the CDC MAC-ELISA, which detects IgM antibodies to ZIKV that appear in ZIKV-infected individuals 4 to 5 days after the start of illness and last for about 12 weeks.³⁸⁴ The test is intended to be used on blood from individuals with a history of symptoms associated with ZIKV or recent travel to an area with active ZIKV transmission.³⁸⁴ Furthermore, a recent novel ZIKV ELISA based on the ZIKV NS1 antigen was also developed and evaluated in European patients for cross-reacting serum antibodies to dengue, yellow fever, hepatitis C, and also tick-borne encephalitis (TBE).²⁰³ The test has particular relevance in Europe, where TBE vaccination coverage is more widespread in certain countries, such as South Germany and Austria, and the test has shown early promise as highly specific and reliable.²⁰³

Another new test has also received FDA EUA.³⁶⁶ The Triplex real-time RT-PCR assay, which was developed by the CDC, is a single-reaction multiplex RT-PCR used to detect ZIKV, chikungunya, and dengue and

was developed to help reduce the diagnostic burden in testing for arboviruses.⁴⁵⁸ Triplex can be used on serum, CSF, urine, and amniotic fluid to test for these three viruses.³⁶⁶ The test strives to improve detection, workflow, and testing costs associated with ZIKV and other arboviral testing; the test also shows initial promise in being able to simplify diagnostic workload for these three arboviruses and was designed to minimize cross-reactivity of testing results between the three viruses.^{366,458} Others have also developed nested, multiplex RT-PCR tests for simultaneous detection of ZIKV, chikungunya, and dengue.⁶² In addition, the US Department of Health and Human Services assisted in funding the development of a rapid ZIKV serologic test (ZIKV Detect IgM Capture ELISA from InBios International) that can diagnose ZIKV in 4 hours, which is much faster than the current serologic test used by the CDC, which takes 2 to 3 days.^{2,195} This rapid serologic test received FDA EUA. However, recent FDA warnings have been issued about high false-positive rates observed.^{145,489}

ZIKV Diagnostic Definitions and Testing Guidelines

Note that CDC interim guidelines for ZIKV testing may change. Therefore it is highly recommended that the most updated guidelines be reviewed to guide any clinical evaluation of patients with suspected ZIKV infection. See <http://www.cdc.gov/zika/hc-providers/index.html>.

BOX 176H.1 Possible Results of Plaque Reduction Neutralization Antibody Testing

The following result interpretations from plaque reduction neutralization antibody testing (PRNT) testing are possible for Zika and dengue based on the detection of immunoglobulin M (IgM) by enzyme-linked immunosorbent assay (ELISA) and the levels of neutralizing antibody titers identified in the PRNT. The results given here will be determined by the laboratories performing PRNT.

Interpretation of Antibody Testing^{a,b}

Recent Zika virus infection^c
 Recent dengue virus infection^c
 Recent flavivirus infection; specific virus cannot be identified^c
 No evidence of Zika virus or dengue virus infection
 Evidence of Zika virus infection; timing cannot be determined^d
 Evidence of dengue virus infection; timing cannot be determined^d
 Evidence of flavivirus infection; specific virus and timing cannot be determined^d
 Presumptive recent Zika virus infection^{c,d}
 Presumptive recent dengue virus infection^{c,d}
 Presumptive recent flavivirus infection^{c,d}
 Equivocal results^d
 Inconclusive results^d
 No evidence of recent Zika virus or dengue virus infection

Report any positive or equivocal IgM Zika or dengue results to state or local health department. PRNT is not currently routinely recommended in Puerto Rico for specimens that have “positive, presumptive, equivocal or possible” Zika interpretations based on testing with current Emergency Use Authorization Zika IGM tests.

^aFor persons with suspected Zika virus disease, Zika virus RNA nucleic acid amplification tests should be performed on specimens collected <14 days after onset of symptoms.

^bTo resolve false-positive results that might be caused by cross-reactivity or nonspecific reactivity, presumptive positive Zika IgM results should be confirmed with PRNT titers against Zika, dengue, and other flaviviruses to which the person might have been exposed.

^cIn the absence of RNA nucleic acid amplification testing, negative IgM or neutralizing antibody testing in specimens collected <7 days after illness onset might reflect collection before development of detectable antibodies and does not rule out infection with the virus for which testing was conducted.

^dZika IgM positive result is reported as “presumptive positive” to denote the need to perform confirmatory PRNT.

Modified from Rabe IB, Staples JE, Villanueva J, et al. Interim guidance for interpretation of Zika virus antibody test results. *MMWR Morb Mortal Wkly Rep*. 2016;65(21):543-546.

Diagnostic Definitions of ZIKV Cases

According to the 2016 WHO interim ZIKV disease definitions, a probable case is a suspected case (signs and symptoms as described earlier) with the presence of IgM antibody against ZIKV and an epidemiologic link (e.g., contact with a confirmed case, or a history of residing in or traveling to an area with local transmission of ZIKV within 2 weeks before the onset of symptoms).³³⁰ A confirmed case is defined as the presence of ZIKV RNA or antigen in serum or other samples (e.g., saliva, tissues, urine, whole blood), or a positive IgM antibody against ZIKV and PRNT₉₀ for ZIKV with a titer of 20 or higher and ZIKV PRNT₉₀ titer ratio of 4 or higher compared with other flaviviruses, and the exclusion of other flaviviruses.³³⁰

Similarly, according to CDC guidelines, laboratory evidence of ZIKV infection includes the following: (1) detectable ZIKV, ZIKV RNA, or ZIKV antigen in any clinical specimen; and (2) positive ZIKV IgM with confirmatory antibody titers that are fourfold or more higher than dengue virus neutralizing antibody titers in serum or cerebrospinal fluid. Testing is considered inconclusive if titer criteria are not met.¹⁵¹ Negative results from a molecular ZIKV test (i.e., ZIKV PCR) does not exclude a diagnosis of ZIKV infection, and ZIKV serology (ZIKV IgM) testing should also be done.⁷²

For congenital ZIKV cases, the CDC considers a positive infant serum or urine ZIKV RT-PCR result as confirmatory for the diagnosis of congenital ZIKV,³⁹⁵ whereas a positive ZIKV IgM result with a negative ZIKV RT-PCR is suggestive of “probable” congenital ZIKV infection.³⁹⁵ As discussed previously, congenital ZIKV infection is a cause of

microcephaly along with other anomalies, including intracranial calcifications and other brain or eye abnormalities, but the full clinical spectrum of ZIKV effects in pregnancy is still under determination.³⁹⁵ (See earlier descriptions of findings that may be seen in congenital ZIKV syndrome.) In addition, it should again be noted that a negative PCR test result may confirm infection but does not necessarily rule out congenital ZIKV infection.³⁹⁵

General Guidelines for ZIKV Testing

The CDC recommends ZIKV testing for any *symptomatic* person who meets one of the following criteria: (1) currently lives in an area identified as having active ZIKV transmission, or (2) has recently returned from travel to an area identified as having active ZIKV transmission, or (3) has had unprotected sex with a partner with confirmed ZIKV infection.³⁶³ With regard to sexual transmission of ZIKV, it is currently not recommended to test blood, semen, female genital tract, or urine as a means to risk-stratify a male or female's likelihood of transmitting ZIKV through sexual intercourse given the current limited knowledge regarding ZIKV's sexual transmission.^{341,363}

ZIKV testing in pregnancy was previously recommended for both symptomatic and asymptomatic women with possible exposure to ZIKV (a history of recent travel to an area with active transmission, residing in an area with active ZIKV transmission, or having had unprotected sexual activity with a partner with confirmed ZIKV infection). Further details of testing and management of ZIKV in pregnancy are beyond the scope of this chapter and are consistently changing.^{313,354} Refer to specific CDC guidelines and testing algorithms for further details on testing during pregnancy. There are different algorithms available for pregnant women traveling to or residing in regions with local ZIKV transmission along with accompanying recommendations for repeat testing and serial fetal ultrasounds during pregnancy.

ZIKV Testing for Infants and Children for Suspected Acute ZIKV Infection

For infants or children younger than 18 years, postnatal ZIKV infection should be suspected in the following situations per the CDC: (1) recent travel or residing in areas with active ZIKV transmission in the past 2 weeks or other possible ZIKV exposure (i.e., adolescent with sexual contact with a partner with exposure risk factors); and (2) two or more symptoms of ZIKV infection (i.e., fever, rash, conjunctivitis, or arthralgia).³⁶⁵

Because vertical transmission of ZIKV from mother to child at the time of delivery is also possible, perinatal ZIKV infection should be suspected in infants in the first 2 weeks of life in the following situations: (1) mother with a history of traveling or residing in a region with active ZIKV transmission 2 weeks or less before delivery or exposure through sexual transmission; and (2) infant with at least two or more symptoms consistent with ZIKV infection (fever, rash, conjunctivitis, arthralgia).³⁶⁵

According to the CDC guidelines for testing of children for acute ZIKV infection, if symptoms have been present for less than 2 weeks (14 days), it is recommended to test for ZIKV RNA by RT-PCR on serum and urine.¹⁵¹ A positive ZIKV RT-PCR test confirms infection, but a negative result does not rule out ZIKV infection. If RT-PCR testing is negative or if it is beyond the 2-week period at presentation, serologic testing is recommended, as discussed earlier^{365,377} (see Figs. 176H.10 and 176H.11).

Infant ZIKV Testing for Suspected ZIKV Congenital Infection

The CDC recommends workup for congenital ZIKV infection for the following groups of infants: (1) infants of mothers with laboratory-confirmed ZIKV infection in pregnancy or (2) infants with abnormal examinations or neuroimaging consistent with congenital ZIKV syndrome whose mothers had ZIKV exposure in pregnancy, regardless of maternal ZIKV laboratory results.³⁹⁵

Infant evaluation for congenital ZIKV infection includes both RT-PCR for ZIKV RNA (serum and urine) and serologic ZIKV IgM testing, ideally from infant specimens collected within the first 2 days of life.^{151,395} Although cord blood was initially recommended to be collected along with serum, most updated CDC guidelines from the end of August 2016 *no longer recommend testing* for ZIKV via cord blood given the false-positive results from maternal blood contamination.³⁹⁵ In addition

to serum, newer guidelines also recommend collecting urine for ZIKV RNA RT-PCR testing, as well as consideration for also collecting and testing whole blood for ZIKV RNA RT-PCR testing.⁷² Note that PRNT cannot distinguish between maternal and infant ZIKV antibodies at birth.⁷² Little is known at this time regarding the duration of ZIKV viral shedding in infants with congenital ZIKV infection, although in some congenital infections such as CMV and rubella, shedding (particularly in urine) may be prolonged.³⁹⁵

For infants with positive ZIKV IgM testing, PRNT may be used to confirm ZIKV-specific antibodies.³⁹⁵ However, PRNT cannot reliably distinguish between ZIKV maternal and infant antibodies and may need to be repeated after the child is 18 months or older, at which time maternal antibodies are expected to have waned.³⁹⁵ For children whose initial ZIKV RNA RT-PCR and IgM testing results were negative at birth, PRNT testing may be useful to evaluate for ZIKV congenital infection.⁷² In that situation, PRNT may be used to evaluate for congenital infection in children 18 months or older.¹⁴

In addition, if CSF is collected for other reasons and is available for testing, it is recommended to test CSF for both ZIKV RNA and ZIKV IgM.^{151,395}

Histopathologic evaluation of placenta and umbilical cord with ZIKV immunohistochemical staining on fixed tissue and ZIKV RT-PCR on fixed and frozen tissue (umbilical cord and placenta) are also recommended for infants born to women with confirmed ZIKV infection and should be considered for those born to women with presumptive ZIKV infection.^{151,313} It should be noted as well that a positive result for ZIKV RNA from placenta can confirm maternal ZIKV infection but cannot reliably determine whether congenital infection has also occurred.⁷² If testing of the mother was not performed during pregnancy, it should also be done and should include testing serum for ZIKV IgM and neutralizing antibodies and for dengue virus IgM and neutralizing antibodies.¹⁵¹

In addition, ZIKV testing (RT-PCR and immunohistochemical staining of fixed tissues) should be offered to pregnant women with confirmed or possible ZIKV infection that suffer from fetal loss or stillbirth.³¹³ Further details about laboratory testing protocols are given later, and interpretation of ZIKV testing results are available on the CDC website (<http://www.cdc.gov/zika/state-labs/index.html>).

EVALUATION AND MANAGEMENT OF PEDIATRIC PATIENTS WITH ZIKV

Recommendations for Evaluation and Management of Possible Pediatric ZIKV Cases

In February 2016, the CDC released interim guidelines for the evaluation and management of infants and children with possible ZIKV infection.^{151,423} Subsequent updates (last in August 2016) have been made to these guidelines released for the evaluation and testing of infants with possible congenital ZIKV infection.^{151,395,423} Remember that ZIKV disease is considered a nationally notifiable condition that warrants reporting all confirmed cases to state health departments.^{363,151}

Evaluation of Children for Acute ZIKV Disease

Recommendations for laboratory evaluation were discussed previously in the section ZIKV Testing for Infants and Children for Suspected Acute ZIKV Infection.

Evaluation for Congenital ZIKV Infection

Recommendations for laboratory evaluation were discussed previously in the section Infant ZIKV Testing for Suspected ZIKV Congenital Infection. However, it is important to note that the need for additional evaluation (other tests and evaluation by subspecialists) is based on whether (1) the infant has any findings consistent with congenital ZIKV syndrome or (2) the infant has laboratory-confirmed congenital ZIKV infection (Fig. 176H.12 and Table 176H.6). Note that recommendations for evaluation have been changed from previous CDC guidelines issued before August 2016 and now include a broader definition of possible congenital ZIKV infection beyond that of just microcephaly or intracranial calcifications.^{151,313}

TABLE 176H.6 Interpretation of Results of Laboratory Testing of Infant’s Blood, Urine, and Cerebrospinal Fluid for Evidence of Congenital Zika Virus Infection

rRT-PCR	IgM	Interpretation
Positive	Positive or negative	Confirmed congenital Zika virus infection
Negative	Positive	Probable congenital Zika virus infection ^a
Negative	Negative	Negative for congenital Zika virus infection ^a

IgM, Immunoglobulin M; rRT-PCR, real-time reverse transcriptase polymerase chain reaction.
^aLaboratory results should be interpreted in the context of timing of infection during pregnancy, maternal serology results, clinical findings consistent with congenital Zika syndrome, and any confirmatory testing with plaque reduction neutralization testing. From Russell K, Oliver SE, Lewis L, et al. Update: interim guidance for the evaluation and management of infants with possible congenital Zika virus infection—United States, August 2016. *MMWR. Morb Mortal Wkly Rep.* 2016;65(33):870-878.

For infants born to women with laboratory-confirmed ZIKV infection, a comprehensive physical examination at birth is essential, which includes measurement of head circumference, length, and weight; gestational age assessment; and evaluation for dysmorphic features and neurologic abnormalities.³⁹⁵ They should also have a postnatal head ultrasound and a hearing screen. Infants with laboratory evidence of ZIKV infection but no abnormalities consistent with congenital ZIKV infection should also undergo an ophthalmologic examination and auditory brainstem response hearing evaluation before 1 month of age.³⁹⁵ In contrast, infants with negative ZIKV testing results and no abnormalities consistent with congenital ZIKV infection should continue their routine newborn care³⁹⁵ (Table 176H.7).

In contrast, infants with abnormalities consistent with congenital ZIKV syndrome will need a comprehensive evaluation at birth and may require access to a facility with pediatric subspecialties.³⁹⁵ Before discharge from the hospital at birth, the recommended evaluation includes a complete blood count and a metabolic panel including liver function tests, an ophthalmologist examination, an ABR hearing evaluation, and consideration for additional neuroimaging, as well as evaluation for other genetic conditions and congenital infections. (Refer to Table 176H.7 and Box 176H.2 for more details.) Specifically, for infants with abnormalities and laboratory results consistent with congenital ZIKV infection, additional evaluation by subspecialists, including infectious disease specialist (for other congenital infections), geneticist (for other causes of microcephaly or other abnormalities), neurologist (for additional neurologic evaluation), and endocrinologist (for hypothalamic or pituitary dysfunction), is also recommended in the early newborn period. (See Box 176H.2 for further detail.)

Infants with congenital ZIKV syndrome will require a medical home with access to multiple subspecialists for regular outpatient care and monthly visits for at least the first 6 months of life. (See further details in Box 176H.2.³⁹⁵) Infants should be evaluated for feeding difficulties and may require assistance with lactation, occupational therapy, speech therapy, and nutrition, and they should be evaluated by a gastroenterologist regarding reflux, aspiration, poor suck, and swallowing dysfunction.³⁹⁵ In particular, issues with swallowing dysfunction may be evident as the infant grows.³⁹⁵ Neurologic examinations should be done at 1 and 2 months of age and may require referrals for additional neurologic issues such as sleeping problems and excessive irritability.³⁹⁵ Repeat ophthalmology examination should be done at 3 months of age if earlier results were normal.³⁹⁵ If the ABR before 1 month of age was normal, repeat examination should be done at 4 to 6 months of age.³⁹⁵ Given the risks for hypothalamic dysfunction and pituitary insufficiency, thyroid screening, including thyroid-stimulating hormone and thyroxine (either free T₄ or both total T₄ and estimated free T₄) should also be conducted at 2 weeks of age and 3 months of age.⁴⁰ In addition, growth and development parameters should be monitored at each visit and may require referral to developmental specialists.

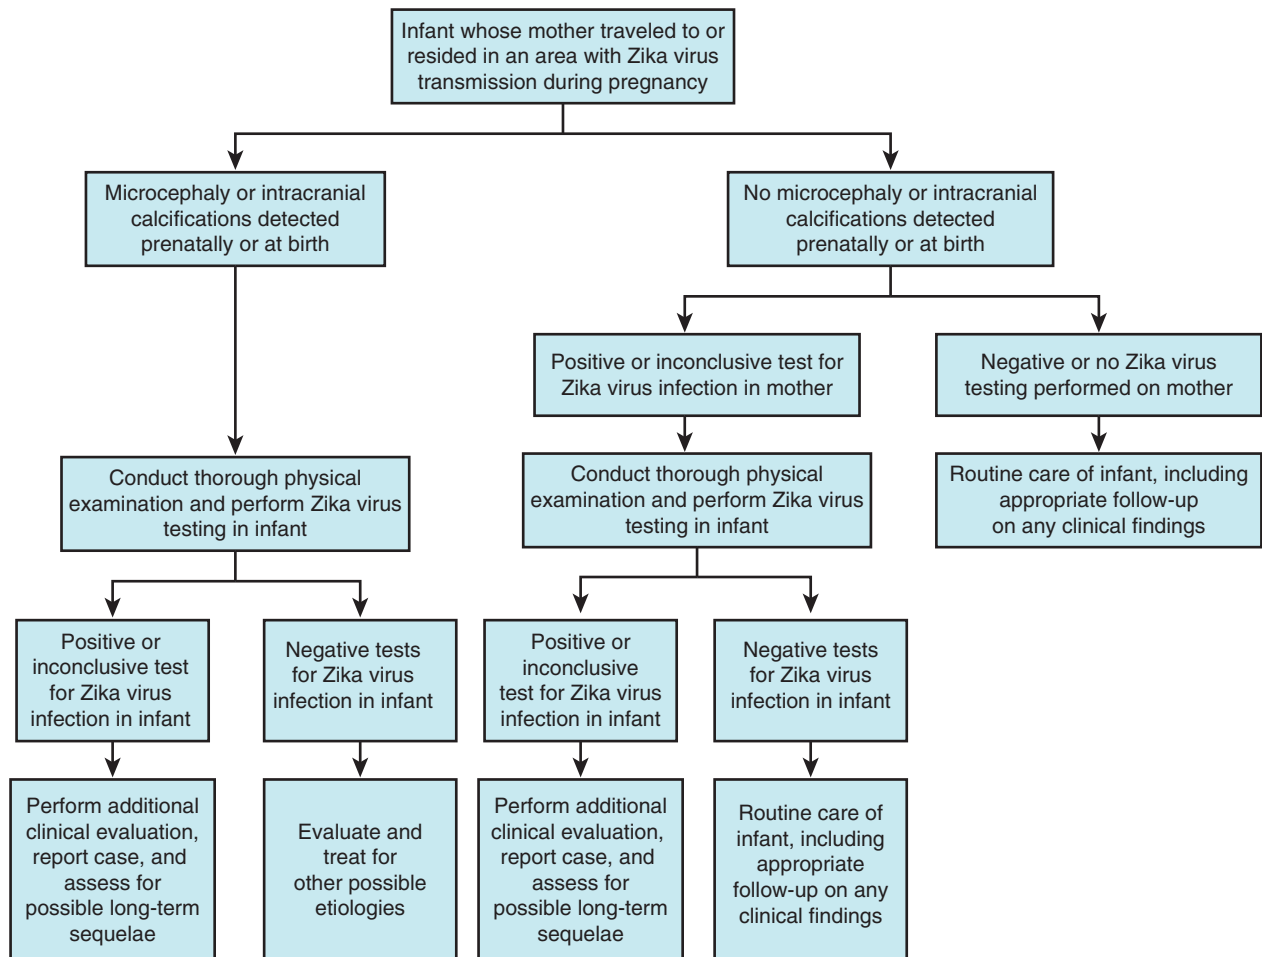

FIGURE 176H.12 Algorithm from the Centers for Disease Control and Prevention (CDC) for Zika virus evaluation of infants born to mothers with Zika virus exposure in pregnancy. Areas with Zika virus transmission are listed on the CDC website at <http://wwwnc.cdc.gov/travel/page/zika-travel-information>. Microcephaly is defined as occipitofrontal circumference less than the 3rd percentile for gestational age and sex based on standard growth curves, not explained by other etiologies. Laboratory evidence of Zika virus infection includes (1) detectable Zika virus, Zika virus RNA, or Zika virus antigen in any clinical specimen; or (2) positive Zika virus immunoglobulin M (IgM) with confirmatory neutralizing antibody titers more than fourfold higher or greater than dengue virus neutralizing antibody titers in serum or cerebrospinal fluid. Testing is considered inconclusive if Zika virus neutralizing antibody titers are less than fourfold higher than dengue virus neutralizing antibody titers. For infants, perform reverse transcriptase polymerase chain reaction (RT-PCR) testing for Zika virus RNA and Zika virus and dengue virus IgM and neutralizing antibodies on serum collected from the umbilical cord or directly from infant within 2 days of birth, if possible. If cerebrospinal fluid is obtained for other reasons, test for Zika virus RNA, Zika virus IgM and neutralizing antibodies, and dengue virus IgM and neutralizing antibodies. Consider histopathologic evaluation of the placenta and umbilical cord with Zika virus immunohistochemical staining on fixed tissue and Zika virus RT-PCR on fixed and frozen tissue. More information on laboratory testing for Zika virus infection is available at <http://www.cdc.gov/zika/state-labs/index.html>. (From Russell K, Oliver SE, Lewis L, et al. Update: interim guidance for the evaluation and management of infants with possible congenital Zika virus infection—United States, August 2016. *MMWR Morb Mortal Wkly Rep.* 2016;65[33]:870-878. Modified from Staples JE, Dziuban EJ, Fischer M, et al. Interim guidelines for the evaluation and testing of infants with possible congenital Zika virus infection—United States, 2016. *MMWR Morb Mortal Wkly Rep.* 2016;65:63-67.)

In addition, infants with laboratory evidence of congenital ZIKV syndrome but no abnormalities consistent with congenital ZIKV infection should also have close outpatient follow-up. They should be monitored for neurologic issues (e.g., seizures and cognitive delay) and for vision and hearing abnormalities.³⁹⁵ Refer to [Table 176H.7](#) and [Box 176H.3](#) for detailed recommendations regarding follow-up for development, ophthalmology, and hearing evaluations during infancy for this particular group of infants.³⁹⁵

Any confirmed or suspected ZIKV cases should be relayed to local, state, or territorial health departments, which will assist in the coordination of laboratory testing and in the prevention of potential risks for local transmission of ZIKV in regions where *Aedes* spp. mosquitoes are

found.^{151,423} To help facilitate better understanding of ZIKV infection, the CDC has established a US Zika Pregnancy Registry to collect information about pregnancy and outcomes for women and their infants with laboratory diagnosis of ZIKV infection.

Health care providers who suspect congenital ZIKV infection in an infant should contact their state, tribal, local, or territorial health department if the infant meets the clinical criteria for testing as outlined in the CDC guidelines. The state, tribal, local, or territorial health department can facilitate laboratory testing for ZIKV infection in infants who meet these clinical criteria. A similar system (Zika Active Pregnancy Surveillance System) has also been established by the CDC in Puerto Rico.³⁶³ In addition, health care providers can contact the CDC Zika

BOX 176H.2 Initial and Outpatient Evaluation and Management of Infants With Laboratory Evidence of Zika Virus Infection and Abnormalities Consistent With Congenital Zika Virus Syndrome

Initial Clinical Evaluation and Management

- Consultation with:
 - Neurologist for determination of appropriate neuroimaging and additional evaluation.
 - Infectious disease specialist for diagnostic evaluation of other congenital infections (e.g., syphilis, toxoplasmosis, rubella, cytomegalovirus infection, lymphocytic choriomeningitis virus infection, and herpes simplex virus infection)
 - Ophthalmologist for comprehensive eye examination and evaluation for possible cortical visual impairment before discharge from the hospital or within 1 month of birth
 - Endocrinologist for evaluation of hypothalamic or pituitary dysfunction
 - Clinical geneticist to evaluate for other causes of microcephaly or other anomalies if present
- Consider consultation with:
 - Orthopedist, physiatrist, or physical therapist for the management of hypertonia, clubfoot, or arthrogryposic-like conditions
 - Pulmonologist or otolaryngologist for concerns about aspiration
 - Lactation specialist, nutritionist, gastroenterologist, or speech or occupational therapist for the management of feeding issues
- Perform auditory brainstem response to assess hearing.
- Perform complete blood count and metabolic panel, including liver function tests.
- Provide family and supportive services.

Outpatient Management

- A medical home should be established, and visits with primary care provider should occur monthly for at least the first 6 months of life.
 - Follow growth parameters; monitor development; provide routine immunizations, anticipatory guidance, and psychosocial support; and ensure infants receive necessary testing and consultations.
- Neurologic examination by the primary care provider at 1 and 2 months of age. Refer to neurology for any abnormalities, or for any parental or provider concerns.
- Refer to developmental specialist and early intervention services.
- Repeat comprehensive ophthalmologic examination at age 3 months, and refer to ophthalmology for any abnormal findings, or for any parental or provider concerns.
- Repeat auditory brainstem response testing at age 4 to 6 months, and refer to audiology for any abnormal findings or for any parental or provider concerns.
- Repeat testing for hypothyroidism at age 2 weeks and age 3 months, even if the initial testing results were normal. Refer to endocrinology for any abnormal findings.
- Provide family and supportive services.

From Russell K, Oliver SE, Lewis L, et al. Update: interim guidance for the evaluation and management of infants with possible congenital Zika virus infection—United States, August 2016. *MMWR Morb Mortal Wkly Rep*. 2016;65(33):870-878.

Pregnancy Hotline (previously available through CDC's Emergency Operations Center watch desk at 770-488-7100, ZikaMCH@cdc.gov or ZikaPregnancy@cdc.gov) to discuss information on infants suspected of having congenital ZIKV infection.

Management of Pediatric Patients Infected With Acute ZIKV

Although a few isolated case reports of fatalities have been reported in the literature, acute ZIKV infection in children is typically mild, with

symptoms usually resolving in 1 week.¹⁵¹ At this time, no specific ZIKV-directed therapies exist, and the mainstay of treatment for acute infection involves supportive care, which primarily constitutes bed rest, maintenance of hydration with appropriate fluids, and symptomatic treatment for pain and fever.^{151,217} For example, acetaminophen has been used for fever and antihistamines have been used to alleviate symptoms of pruritus that often accompany patients with rash.²¹⁷ However, it should be noted that nonsteroidal antiinflammatory drugs (NSAIDs) are not recommended until dengue virus is ruled out given the overlap in presentation of ZIKV and dengue, which may pose a risk for hemorrhagic complications.¹⁵¹ It is also recommended that NSAIDs be avoided in children younger than 6 months given the potential risk for nephrotoxicity, particularly for children with dehydration.²¹⁷ In particular, use of aspirin and other salicylates should be avoided in children with acute viral illnesses given the potential association with Reye syndrome.¹⁵¹ Recommendations from the CDC will continue to evolve as more information is available to inform recommendations in the care of pediatric patients.¹⁵¹

Note that the diagnosis and management of acute ZIKV in pregnant women is beyond the scope of this textbook. The CDC has multiple published interim guidelines available in greater detail on its website that are continually updated (<http://www.cdc.gov/zika/hc-providers/qa-pregnant-women.html>).

ZIKV PREVENTION: VECTOR CONTROL, VACCINES, AND OTHER CHALLENGES

Transmission Prevention

Mosquito Vector Control

Prevention of ZIKV infection and other arboviral infections, including dengue and chikungunya, is primarily focused on the prevention of mosquito bites when traveling or living in regions with active ZIKV transmission. Information on the current areas with active ZIKV transmission is available on the CDC website, <http://wwwnc.cdc.gov/travel/page/zika-travel-information>.

Appropriate mosquito protection is especially critical during the daytime because *Aedes* species are typically daytime feeders but differ from others such as *Culex* species, which are carriers of West Nile virus and are primarily active evening to morning, and *Anopheles* species, which may transmit malaria and primarily bite from dusk to dawn.²³⁶ Recommended means of mosquito bite prevention include barrier methods to cover exposed skin, such as wearing long-sleeved shirts, pants, and hats, and the use of permethrin-treated clothing and insect repellents.¹⁵¹ Substances such as DEET (*N,N*-diethyl-*m*-toluamide), picaridin (which is a long-acting repellent), oil of lemon eucalyptus, or ethyl butylacetylaminopropionate (IR3535) provide protection against mosquito bites.^{151,217} Of these, DEET appears to have the best track record (longest history and most studied) of providing the most long-acting and effective protection.^{236,474} DEET is considered safe to use in pregnant women and children, and its use in these groups was reviewed by the US Environmental Protection Agency (EPA) in 1998 and again in 2014.⁴⁷⁴ Local reactions involving the skin are the primary adverse effects reported with DEET use.⁴⁷⁴ After DEET, picaridin comes in second with regard to the strength of evidence supporting its use as an effective mosquito repellent.³⁵⁰

Most insect repellents that can protect against mosquito bites and meet registration criteria with the EPA can be safely used in children 2 months and older.¹⁵¹ As such, products with DEET should not be used in children younger than 2 months.¹⁵¹ The maximum permissible concentration for DEET for use on infants and children is 30%, and efforts should be made to avoid contact of the product with children's hands, eyes, mouth, and areas of open skin.^{151,217} The CDC recommends against the use of oil of lemon eucalyptus on children younger than 3 years.^{151,217} Screening on windows and doors to prevent mosquitoes from entering residences and mosquito netting for bedding in rooms while sleeping with lack of adequate window and door screening methods or air-conditioning can also be used to prevent mosquito contact and thereby transmission of infections.^{151,217}

In addition, prevention of additional mosquito bites in infants, children, and any persons already infected with ZIKV is especially

TABLE 176H.7 CDC Updated Initial Evaluation and Recommended Outpatient Management in First Year of Life for Infants With Possible Congenital Zika Virus

Mother	Infant Clinical Exam	Before Hospital Discharge	Infant Testing	2 wk	1 mo	2 mo	3 mo	4–6 mo	9 mo	12 mo
Laboratory evidence of Zika virus infection ^a	No evidence of abnormalities	Routine newborn care: PE, HC, weight/length, and neurologic exam Hearing screen Head ultrasound Infant Zika virus testing	Negative for Zika virus infection Laboratory evidence of Zika virus infection ^a	Routine care, including monitoring of developmental screening Ophthalmology exam ABR				Consider ABR repeat	Behavioral audiology if ABR not done at 4–6 mo	
	Abnormalities consistent with congenital Zika syndrome	As above, plus: Consider transfer to hospital with subspecialty care CBC, metabolic panel, LFTs, ophthalmology exam ABR	Negative for Zika virus infection Laboratory evidence of Zika virus infection ^a	Monitoring of OFC and development at every visit and age-appropriate developmental screening Evaluate for other causes of congenital anomalies Further management as clinically indicated Thyroid screen Neurologic exam Thyroid screen, ophthalmology exam Routine preventive health care including monitoring of feeding and growth Routine and congenital infection-specific anticipatory guidance Referral to specialists, including evaluation of other causes of congenital anomalies as needed Outpatient management for appropriate infant clinical exam and test results						
Not tested, or tested outside of appropriate window	No evidence of abnormalities	Consider advanced neuroimaging Maternal Zika virus testing ^b Consider Zika virus placental testing Routine newborn care: PE, HC, weight/length and neurologic exam Hearing screen Head ultrasound	Perform infant Zika virus testing of evidence of Zika virus infection on maternal testing ^{a,b}							
	Abnormalities consistent with congenital Zika syndrome	As above, plus: Consider transfer to hospital with subspecialty care CBC, metabolic panel, LFTs, ophthalmology exam ABR Consider advanced neuroimaging Infant Zika virus testing	Negative for Zika virus infection Laboratory evidence of Zika virus infection ^a	Evaluate for other causes of congenital anomalies Further management as clinically indicated Refer to outpatient management for infant with abnormalities consistent with congenital Zika syndrome						

^aLaboratory evidence of maternal Zika virus infection includes (1) Zika virus RNA detected by real-time reverse transcriptase polymerase chain reaction (RT-PCR) in any clinical specimen; or (2) positive Zika virus immunoglobulin M (IgM) with confirmatory neutralizing antibody titers. Confirmatory neutralizing antibody titers are needed in addition to IgM for maternal Zika virus infection.

^bMothers should be tested by RT-PCR within 2 weeks of exposure or symptom onset, or by IgM within 2–12 weeks of exposure or symptom onset. Because of the decline in IgM antibody titers and viral RNA levels over time, negative maternal testing 12 weeks after exposure does not rule out maternal infection.

ABR, Auditory brainstem response; CBC, complete blood count; CDC, Centers for Disease Control and Prevention; LFTs, liver function tests; HC, head (occipitofrontal) circumference; PE, physical examination.

From Oduyebo T, Igbimosa I, Peterson EE, et al. Update: interim guidance for health care providers caring for pregnant women with possible Zika virus exposure—United States, July 2016. *MMWR Morb Mortal Wkly Rep*. 2016;65:739-744. Russell K, Oliver SE, Lewis L, et al. Update: interim guidance for the evaluation and management of infants with possible congenital Zika virus infection—United States, August 2016. *MMWR Morb Mortal Wkly Rep*. 2016;65(33):870-878.

BOX 176H.3 Outpatient Management of Infants With Laboratory Evidence of Zika Virus infection but No Abnormalities Consistent With Congenital Zika Virus Syndrome

- A medical home should be established.
 - Follow growth parameters and perform developmental screening at each well-child visit.
 - Emphasize anticipatory guidance for families regarding developmental milestones, feeding and growth, sleep and irritability, and abnormal movements.
- Use a standardized, validated developmental screening tool at 9 months as currently recommended, or earlier for any parental or provider concerns.
- Referral to ophthalmology for comprehensive eye examination within 1 month of birth. Perform vision screening and assess visual regard at every well-child visit and refer to ophthalmology for any abnormal findings or for any parental or provider concerns.
- Perform auditory brainstem response within 1 month of birth. Consider repeat auditory brainstem response at age 4 to 6 months or perform behavioral diagnostic testing at age 9 months and refer to audiology for any abnormal findings or for any parental or provider concerns.
- Provide family and supportive services.

From Russell K, Oliver SE, Lewis L, et al. Update: interim guidance for the evaluation and management of infants with possible congenital Zika virus infection—United States, August 2016. *MMWR Morb Mortal Wkly Rep.* 2016;65(33):870-878.

important during the first week of illness.¹⁵¹ During this time, infected individuals are more likely to be viremic, and any mosquito bites during this period are more likely to perpetuate the human-mosquito-human cycle of ZIKV transmission, which has allowed ZIKV to flourish in many densely populated urban areas around the world.¹⁵¹ This also applies to returning travelers from ZIKV endemic regions because most ZIKV infections appear to be asymptomatic.²³⁶

Additional guidance on mosquito bite prevention is also available on the following EPA and CDC websites:

- <http://www.cdc.gov/zika/prevention>
- <http://wwwnc.cdc.gov/travel/yellowbook/2016/the-pre-travel-consultation/protection-against-mosquitoes-ticks-other-arthropods>
- <http://www.epa.gov/insect-repellents/using-insect-repellents-safely-and-effectively>

Another critical part of vector control includes efforts to remove potential sources of mosquito breeding in endemic areas. In fact, some experts believe that clearing mosquito breeding sites around the home is the most crucial component in effective mosquito control for ZIKV, more efficacious than mass-spraying towns or cities because of *Aedes* spp. mosquitoes' tendency to prefer breeding in artificial containers.¹⁶⁹ Unfortunately, *Aedes* spp. mosquitoes are extremely well adapted to coexist near human habitation; they breed well in the artificial containers with even minimal amounts of water that often surround homes.³³² Instructions regarding mosquito control at home are available on the CDC website (<http://www.cdc.gov/zika/prevention/controlling-mosquitoes-at-home.html>) but primarily include removing any sources collecting standing water.²³⁶

Mosquito control at the city level is also important. After the discovery of the first locally acquired ZIKV cases in the United States (Florida), the CDC implemented a combination of the strategies listed previously in an effort to limit the spread of ZIKV. Mosquito control strategies deployed included use of larvicides and insecticides to remove larval and adult mosquitoes, aerial spraying with Naled and larvicide, and removal of standing water.¹⁶¹

Other ZIKV Transmission Considerations

Breast milk transmission: interim guidelines for breast-feeding mothers with ZIKV. The CDC has published preliminary guidelines based on

available data with regard to the safety of breast-feeding for mothers with ZIKV infection.^{151,423} It has been acknowledged that ZIKV RNA and infective viral particles have been recovered from breast milk in mothers with ZIKV infection.^{33,123,151} However, at this time, no cases of infant ZIKV acquired through breast-feeding have been reported.^{151,423} It is believed that, based on available evidence, the benefits that come with breast-feeding are greater than theoretical risks for ZIKV transmission to infants through breast milk.¹⁵¹ As such, the CDC continues to support breast-feeding for ZIKV-infected mothers currently living in regions with active ZIKV transmission.¹⁵¹

Other ZIKV transmission risks: sexual transmission, blood transfusion, and travel. ZIKV has been detected in semen and female genital fluid,^{98,353,379} and most sexual transmission has been reported from symptomatic ZIKV cases, including male-to-female or male partners and from female-to-male partners.^{22,251,390,442} However, two cases have suggested the potential for ZIKV to be transmitted sexually from an asymptomatic carrier.^{49,160,353} It is not known at this time whether detection of ZIKV in semen reflects any adverse effects on spermatozoa or negatively impacts future semen quality and fertility.³⁸¹

To reduce the risk for sexual ZIKV transmission to pregnant partners, it is recommended that males who live in or have recently traveled to an area with ZIKV transmission, abstain from sexual activity or use condoms with pregnant partners throughout the duration of pregnancy, particularly in regions where local ZIKV transmission is actively occurring.^{217,340,353,354} This is particularly important because sexual transmission may occur even in the absence of symptoms. The CDC and WHO recommend that men both with and without symptoms who are returning from regions with local ZIKV transmission use condoms or abstain from sexual activity for at least 6 months after return from travel or after symptom onset to prevent ZIKV transmission to partners.^{50,332,353} Infected females should abstain from sexual activity or use condoms for at least 8 weeks from symptom onset to prevent ZIKV sexual transmission to others.^{50,332,340,354} It should be noted that the 6-month guideline for prevention of ZIKV sexual transmission from men was based on the initial finding that ZIKV was detected in semen up to 62 days multiplied by a factor of 3.²⁵⁹ However, given more recent reports that ZIKV has been detected in semen 80 to 188 days after symptom onset, some experts question whether this may warrant extending this interval to at least 9 months.^{252,253,259,309}

Women who have recently traveled to regions with ZIKV local transmission and do not have symptoms are advised to wait at least 8 weeks before planning a pregnancy.^{332,340,354} Men, regardless of symptoms, should wait at least 6 months.³⁵³ If one of the partners has ZIKV clinical illness or confirmed ZIKV infection, the WHO recommends waiting at least 6 months before attempting conception; similar recommendations have been made by the CDC, but with differences in the duration of waiting before attempts at conception for men (at least 6 months) and women (at least 8 weeks) with ZIKV infection.^{332,340,354}

Additional details and updates are available on the CDC and WHO website (<http://www.cdc.gov/zika/transmission/sexual-transmission.html>).

It is also recommended by the CDC that pregnant women avoid travel to areas with continued ZIKV transmission.²¹⁷ Updated travel notices from the CDC are available on their website (<http://wwwnc.cdc.gov/travel/notices>).

Deferral of blood donations is also recommended for individuals that have recently traveled to regions with ZIKV transmission with or without confirmed ZIKV infections.²¹⁷

As with many other infections, standard precautions should be taken in the care of patients and family members with ZIKV infection.³⁶⁸ Of note, an unusual case of secondary nonsexual ZIKV transmission, possibly through mucocutaneous contact with sweat or tears of a ZIKV-infected patient with high levels of ZIKV viremia, also underscores the importance for health care workers to adhere to standard precaution procedures in the care of ZIKV patients.^{48,428} Refer to the CDC for more detailed guidance on this matter (<https://www.cdc.gov/zika/hc-providers/infection-control.html>).

Vaccine Development

The ability of effective antiviral vaccines to combat devastating congenital viral infections is best exemplified with the successes of the rubella

vaccine, which has virtually eliminated congenital rubella syndrome in countries with a high level of vaccine coverage.³⁴⁴ A similar strategy could be employed with ZIKV after an effective vaccine is available.³⁴⁴ However, at present, no approved vaccines against ZIKV exist.

Yet, after declaration by the WHO that ZIKV was a global public health emergency, multiple organizations have joined efforts, and creating a ZIKV vaccine is now considered a leading research priority around the world.^{333,440} This ZIKV vaccine collaborative includes 18 active programs comprising five academic groups and 15 commercial groups that are researching different strategies to create a successful ZIKV vaccine (purified inactivated virus vaccine; nucleic acid–based [RNA, DNA] vaccine; live, vectored vaccine; subunit vaccine; viruslike particles [VLP] vaccine; and live, recombinant vaccine) that build on existing flavivirus knowledge and technology.^{83,221,333,333,382,440}

Some vaccine experts believe that developing an effective ZIKV vaccine is foreseeable given that vaccines exist for several other flaviviruses, including yellow fever, Japanese encephalitis, and dengue, which are all live, attenuated vaccines.^{83,440} Yet, important questions that will help guide this process include determining whether infection will lead to lifelong immunity, whether other related flaviviruses may have the potential to provide any cross-protection against ZIKV, and whether an appropriate primate model or other animal models to evaluate ZIKV vaccines can be developed.^{46,83} Other potential hurdles include ZIKV's ability to cause neurologic complications such as GBS and the potential for complications related to antibody-dependent enhancement seen with its close relative, dengue,²²⁰ which will require exercising prudence and caution during the development and testing of any successful vaccine candidates.³⁴⁴ This will also need to be balanced with the importance of providing protection in special populations such as pregnant women. Other challenges include the possibility that ZIKV spread has already peaked in countries such as Brazil and Colombia, resulting in herd immunity that may make it more difficult to perform vaccine clinical trials to evaluate vaccine efficacy.⁸³

The first human trials (phase I study) of a ZIKV vaccine (Inovio Pharmaceuticals), a DNA vaccine, began in the end of July 2016.⁸³ Other vaccines (three, including another ZIKV DNA vaccine, which has a genetically engineered plasmid that encodes premembrane [prM] and envelope [E] ZIKV structural proteins that then allow release of viruslike subviral particles that can trigger an immune response) created in collaboration with NIAID, Walter Reed, Sanofi Pasteur, and Butantan Institute in Brazil are also in development.^{2,83,118} Among these, the NIAID ZIKV DNA vaccine has already begun phase I clinical trials with testing in at least 80 volunteers for immune response and vaccine safety and plans to enter phase II clinical trials in 2017.^{2,310} The vaccine was designed after previously developed NIAID investigational West Nile virus vaccines.³¹⁰ Another whole-particle inactivated ZIKV vaccine will also begin phase I clinical trials.²

In addition, in August and September 2016, it was reported that another research group, which had developed several ZIKV vaccines (three different platforms) used in rhesus monkeys, had demonstrated protection against ZIKV.^{3,83} These ZIKV vaccines showing preliminary success by producing ZIKV neutralizing antibodies included (1) an inactivated ZIKV vaccine, (2) a plasmid DNA vaccine, and (3) a recombinant rhesus adenovirus serotype 52 vector vaccine.³ Earlier studies had also demonstrated protection using these vaccines (purified inactivated ZIKV vaccine and plasmid DNA vaccine) in mice model challenges.^{3,235} Vaccine-induced antibodies against ZIKV also provided protection against ZIKV in ZIKV challenge studies.³ A list of candidate vaccines, including institution, vaccine category, and stage of development, are available from the WHO and other reviews.^{333,382}

Future Therapeutics, Vector Control, and Other Interventions to Address ZIKV

Therapeutics

Although considerable efforts have already jump-started the development of vaccines against ZIKV, the role of developing new antiviral therapeutics, although theoretically important, has been deemed less of a priority by the WHO given current limitations in understanding the virus, clinical

progression of disease, and pathogenesis of the infection.³³³ However, some therapeutic agents that may be further evaluated in the future or are under development and have variable activity against some flaviviruses include amodiaquine, chloroquine, ribavirin, interferon- α , BCX4430 (Biocryst), GS-5734 (Gilead), and NITD008.³³³

In addition, because the development of new drugs is time-consuming and expensive, one strategy used to expedite drug discovery in ZIKV has included repurposing drugs by screening other FDA-approved drugs for ZIKV activity.⁸¹ One research group did this by screening 774 FDA-approved drugs to determine whether they had activity in vitro against ZIKV and found that more than 20 of these drugs had some activity against ZIKV.²⁹ These included anti-flavivirus drugs (bortezomib, mycophenolic acid, ivermectin), as well as others (daptomycin, micafungin, clofazimine, mebendazole, mefloquine, pyrimethamine) whose antiviral activity was not previously known.²⁹ Of these, mycophenolic acid and daptomycin had high activity against ZIKV.²⁹ Some of the drugs had activity against ZIKV in several human cell types (placental, cervical, and neural stem cells).^{29,81} ZIKV's role in cell cycle and proapoptotic paths may be one reason that drugs used in cancer treatment have also shown in vitro activity against ZIKV.⁸¹ A similar study was performed by another group that screened 6000 compounds for potential to inhibit ZIKV or protect ZIKV-infected cells from death (by inhibiting caspase-3 activity) in neural cells. This group identified 116 compounds and confirmed that 35 showed potential to inhibit ZIKV replication or cellular death, with notable ones including niclosamide (anthelmintic drug) and emricasan (caspase inhibitor); combined treatment with compounds from both categories also enhanced protection.^{1,94,475} However, issues with many of these compounds in both studies include having antiviral activity that may also be accompanied by cell death, belonging to known classes of pregnancy teratogens (category D drugs), having immunosuppressive effects that may encourage virus persistence, and even having concentration-dependent antiviral effects that may enhance the virus at higher concentration, which was seen with daptomycin.^{29,94,475}

Others have also begun to investigate the effects of hepatitis C (member of the flavivirus family) drugs on the ZIKV polymerase (NS5, a RNA-dependent RNA polymerase) with nucleotide inhibitors (sofosbuvir, ribavirin, and IDX-184 and MK0608 as nucleotide inhibitors against HCV polymerase), which have shown some preliminary promise in activity against ZIKV.^{131,396} Similar studies have evaluated other nucleoside analogs for in vitro activity against ZIKV's RNA-dependent RNA polymerase that are currently in use to treat other types of infection such as HIV, hepatitis B, CMV, and herpes simplex virus, with 2'-C-methylated nucleosides showing some preliminary promise.¹³⁵ Bithionol, which inhibits host caspases, has also shown broad activity against a variety of bacterial toxin pathogenic effects as well as ZIKV.²⁴²

Given the difficulties of testing new therapeutic drugs in pregnant women, the WHO early on had anticipated that therapeutics for use in pregnancy will not be a research and development priority, apart from the potential development of prophylactic interventions or passive immunization therapies.³³³ Possibilities for such immunotherapies include the use of pooled immunoglobulin from heterologous serum or monoclonal antibodies to aid in ZIKV neutralization at the blood-placenta barrier.³³³ These approaches have been employed for other viral in utero infections such as CMV and HIV.³⁴⁴ A list of several potential drug therapy candidates currently under investigation are available from several reviews.^{333,382}

Vector Control

ZIKV is one of the many vector-borne diseases that have been estimated to account for 22% of the communicable global disease burden.³³³ Vector control efforts have demonstrated their ability to reduce and halt disease transmission in endemic regions.³³³ Novel tools that aid in mosquito control to employ in the battle against ZIKV include several different strategies: (1) mechanical approaches (e.g., ovitraps, which mimic preferred *Aedes* spp. breeding sites); (2) chemical approaches (e.g., development of chemical agents with adulticidal and larvicidal properties, including investigation of plant-based secondary metabolites with insecticide properties such as alkaloids derived from Amaryllidaceae plants, novel approaches to outdoor spraying, and others); (3) biologic

approaches (e.g., use of bacteria such as *Bacillus thuringiensis*, *Bacillus israelensis*, and *Wolbachia* species that can reduce transmission of arboviruses in mosquitoes), fungal control (e.g., *Metarhizium anisopliae* and *Beauveria bassiana* biocontrol activity against *Aedes* species), copepod predators (e.g., fish that feed on mosquito larvae), or Sterile Insect Technique through irradiation of male mosquitoes; and (4) genetic approaches (e.g., Sterile Insect Technique, creation of insects with dominant lethal genes [RIDL], RNAi-boosted insect immune responses that lead to sterility and inhibit female insect development, and homing endonuclease genes (gene drives to limit ability to transmit pathogens)).^{258,325,333} A WHO Vector Control Advisory Group has also been convened to review new tools and strategies that may be relevant to addressing the ZIKV global public health crisis.³³³

CONCLUSION

Although ZIKV represents a formidable global health challenge, it was initially met by an impressive and early response from public health and scientific leaders around the world. To catalyze and strengthen global commitment to fighting ZIKV, the WHO had created the Zika Strategic Response Framework. The goals included defining and prioritizing research into ZIKV by bringing experts and partners together, enhancing surveillance and potential complications, strengthening capacity to engage communities to increase understanding of ZIKV risks, improving laboratory capacity to detect ZIKV effectively, supporting health authorities to implement vector control to reduce *Aedes* mosquitoes, and creating recommendations for clinical management and follow-up of those with ZIKV complications.^{332,490} As a major step in this direction, the WHO, along with multiple international organizations, convened an International ZIKV Summit at the Institute Pasteur in Paris, France in April 2016. Scientists and public health professionals from around the world came together to discuss key issues surrounding this ZIKV Public Health Emergency, which included topics such as epidemiology and clinical cohorts, neurologic complications, vaccine development, diagnostics, animal models, and vector control.³²⁴

By October 2016, the WHO had effectively convened four Emergency Committee meetings on ZIKV and microcephaly and had received nearly \$24 million dollars in contributions from 13 major global donors to combat ZIKV. The rapid response of the scientific community has also been laudatory. Nearly 1 year since declaring ZIKV a public health emergency, a flurry of scientific reports has been generated with more than 2000 ZIKV publications available on the US National Library of Medicine Pubmed.gov website alone. By November 2016, the WHO announced that it no longer considered ZIKV a global health emergency.⁴²⁷ Instead, ZIKV would be considered a “significant and enduring public health challenge” requiring a sustained focus of resources and activities within the WHO.⁴²⁷ The WHO’s ZIKV strategic response is estimated to cost more than \$122 million.¹⁷³ Yet, although WHO experts argue that the change in status is actually an escalation in ZIKV’s standing as a global health priority, some critics worry that it may lead to international government and funding apathy.⁴²⁷

Nevertheless, it is clear that the societal and economic costs that the ZIKV epidemic leaves in its wake are tremendous and will continue to grow. Estimates of caring for even one child with microcephaly have been estimated to be as high as \$10 million dollars. By the end of August 2016, in the United States alone, the CDC had already spent \$194 million of the \$222 million dollars received from Congress to respond to the ZIKV threat.^{103,173} The World Bank has estimated that the ZIKV economic losses in 2016 in just Latin America will total more than \$3.5 billion dollars.¹⁷³ To effectively combat ZIKV, it is clear that a sustained, dedicated, and multifaceted approach to prevention, diagnosis, and management will be needed to halt further morbidity and mortality from this emerging pathogen. Issues of economic, gender, and racial/ethnic inequality will all be pushed to the forefront and will need to be addressed effectively as we deal with ZIKV’s global societal ramifications.¹⁷³ As with many other infections, it is women and children, particularly from poor urban regions around the world, that will continue to pay the highest price from ZIKV.^{9,199}

1761 ■ Other Less Commonly Recognized Flaviviruses

Theodore F. Tsai • Gail J. Harrison

The less medically recognized flaviviruses include dozens of arthropod-borne pathogens that may cause life-threatening illness and may potentially become emerging pathogens causing public health problems worldwide. The well-known flaviviruses, such as dengue, West Nile, yellow fever, tick-borne encephalitis, and Japanese encephalitis virus infections, as well as the recently emerged Zika virus, are discussed under their own chapters.^{10,16,21}

POWASSAN VIRAL ENCEPHALITIS

Powassan viral encephalitis is the only zoonotic tick-borne flavivirus detected in North America. Powassan virus was isolated from a fatally

infected patient and named after the patient's Ontario town of residence.⁹ The virus is classified within the antigenic complex of tick-borne flaviviruses, with North American viruses circulating in two genetic lineages in distinct enzootic cycles.^{11,12} More than half of surviving cases suffer from residual neurologic deficits, frequently associated with upper cervical damage leading to upper extremity muscle weakness and wasting. Powassan encephalitis should be considered in the differential of acute childhood encephalitis.

Epidemiology, Ecology, and Pathogenesis

Fewer than 50 sporadic cases of naturally acquired Powassan encephalitis have been reported from North America and others from Russia, as

well as two laboratory-acquired cases. Approximately one fourth of the cases from North America have occurred in children younger than 15 years, and the preponderance of cases have been in males. Most cases have occurred in the summer or early fall, and one patient had an onset in December.^{17,37}

Reported cases have been acquired chiefly in eastern and upper Midwestern US states and Canadian provinces; however, the geographic distribution of the virus is far wider, with strains recorded from West Virginia, Colorado, South Dakota, and California, and serologic evidence of infection in humans or animals reported from Wyoming, Minnesota, North Dakota, British Columbia, Alberta, and Sonora, Mexico.^{4,11,24,41} Since 2008, the number of confirmed cases has increased.⁴ Viral isolates also have been recovered from ticks, mosquitoes, and birds from southeastern Russia, and evidence of viral transmission in China and Southeast Asia has been reported.³³

In North America, viruses in lineage 1 are transmitted to small mammals by *Ixodes cookei* ticks, chiefly to groundhogs, skunks, and weasels; by *Ixodes marxi* ticks mainly to red squirrels; and by *Dermacentor andersoni* ticks to chipmunks.^{11,12} The virus is transmitted transstadially in *D. andersoni* and *Ixodes pacificus*, and transovarial transmission has been shown in other species. Lineage 2 viruses (deer tick virus) are transmitted by *Ixodes scapularis*; however, although infections have been demonstrated in *Peromyscus* mice, details of the viral transmission cycle are poorly defined. Because *I. scapularis* also is the vector of *Borrelia burgdorferi*, *Babesia microti*, and *Anaplasma phagocytophilum*, it is of interest that in a collection of adult ticks from Long Island and Westchester County, New York, 2% were infected with Powassan virus, whereas infection rates for the other pathogens were 64%, 20%, and 20%, respectively.⁵⁰ The absence of a Powassan epidemic paralleling that of Lyme disease suggests differences in the agents' transmission cycles. Because the deer tick virus has been implicated in two fatal Powassan encephalitis cases, it seems unlikely that the strain is less virulent to humans than lineage 1 strains.^{17,49} Russian strains of the virus are identical to lineage 1 viruses, suggesting an introduction from North America within the last century, possibly with the importation of farmed minks.³⁰ *Ixodes persulcatus* and various *Haemaphysalis* ticks are the principal vectors, and *Apodemus* mice and *Microtus* voles are the main vertebrate hosts.

Seroprevalence in humans is low, from less than 1% to 3%. Human infections probably are rare because *I. cookei* ticks usually confine themselves to animal host burrows, limiting opportunities for human exposure. Patients usually give a history of outdoor exposure but, in one case involving a 13-month-old infant, an infected tick was brought into the home by a domestic cat.⁵³ Animal serosurveys indicate that infections occur in dogs, and exposure to ticks on domestic animals may be an alternative source of infection. In a survey of New York goats, 2% had serologic evidence of past Powassan virus infection, which indicates the possibility of raw milk-borne Powassan virus infection in the United States, similar to the alimentary transmission of tick-borne encephalitis from infected raw milk products in Europe.⁵⁵ Although no such cases of Powassan cases infection have been reported, experimental studies have shown that domestic goats can be infected with Powassan virus and can shed the virus into milk.

Clinical and pathologic signs of encephalitis have been produced in experimentally infected horses and mouse models.⁴⁵ In one mouse model, the disease progresses rapidly, with a poliomyelitis-like syndrome with a high level of POWV antigen in the ventral horn of the spinal cord, as well as marked infection of the spleen, suggesting that the lymphoid organs may play an important role in pathogenesis.⁴⁵ Also, unlike Lyme disease and some rickettsial infections, Powassan virus infection can be transmitted after only a brief period of tick attachment.^{11,12}

Clinical Manifestations

The incubation period may be several weeks after known exposure to a tick. Early symptoms of fever, headache, lethargy, vomiting, retro-orbital pain, and photophobia are followed by changes in sensorium, confusion, generalized or focal seizures, progressive weakness, difficulty ambulating and moving limbs, paresis, and paralysis, that may lead to coma and

require ventilator support and intensive care.* Magnetic resonance imaging has shown restricted diffusion and abnormal enhancement in parietal and temporal lobes and thalamic hemorrhage, which is often seen in other forms of flaviviral encephalitis. Approximately 10% of cases have been fatal; however, significant neurologic sequelae follow in the majority of survivors, including hemiplegia, quadriplegia, aphasia, and cognitive impairment. Residual shoulder girdle atrophy and weakness, analogous to sequelae that occur after European and Far Eastern tick-borne encephalitis, are common.⁷ In another patient, wasting and weakness of a leg consistent with lumbosacral poliomyelitis were reported.^{9,25} On the other hand, a laboratory-confirmed case was reported in a febrile patient without neurologic signs.²⁴

Clinical and experimental observations of tick-borne encephalitis suggest that chronic central nervous system infection characterized by a seizure disorder (i.e., epilepsy partialis continua), weakness, and dementia may occur after recovery from the acute phase of illness. A retrospective study of 22 Canadian patients with a similar clinical syndrome and in whom histologic changes in the brain resembled those of chronic tick-borne encephalitis showed no evidence of Powassan virus infection. However, none of these patients had a history of acute encephalitis.

Laboratory Diagnosis

Virus has been recovered from the brains of patients with fatal cases of the disease. A serologic diagnosis can be achieved more rapidly by detecting specific immunoglobulin (Ig)M antibody by IgM antibody capture-enzyme immunoassay (MAC-EIA) in acute-phase serum or spinal fluid. Confirmatory testing using dilution plaque reduction neutralization test (PRNT) can be performed by the Centers for Disease Control and Prevention. Early in the illness, IgM MAC-EIA serologic studies on serum and cerebrospinal fluid (CSF) may be negative.²⁹ Heterologous antibodies from other flavivirus infections (e.g., dengue and West Nile and St. Louis encephalitis and Zika virus) or vaccinations (e.g., tick-borne encephalitis and yellow fever) may interfere with interpretation.

Differential Diagnosis

Powassan encephalitis should be considered in the differential diagnosis of acute childhood encephalitis. The clinical findings of encephalitis in a patient with a history of a tick bite acquired in an endemic area should suggest the possibility of Powassan encephalitis. However, because ixodid tick bites may be inconspicuous, a negative history does not exclude the diagnosis. Other viral agents of encephalitis, especially eastern equine encephalitis virus and California group viruses, which are prevalent in New York State and eastern Canada, should be considered in the differential diagnosis. Lyme disease, because of its known geographic distribution and association with a tick vector, also may be associated with neurologic complications; however, a history of having a typical rash and arthritis should differentiate the conditions. In a series of 145 clinical encephalitis cases at a Canadian tertiary pediatric hospital, one was attributed to Powassan virus.²⁸ Imported travel-associated cases of tick-borne encephalitis acquired in Europe have been reported, underscoring the value of obtaining a travel history.

Treatment and Prevention

No specific therapy for Powassan encephalitis is available. Personal protective measures to avoid tick bites are advised. Consumption of unpasteurized goat milk should be avoided because of the theoretical risk for contracting Powassan virus infection and the well-documented risk for acquiring other infections associated with raw milk. Inactivated tick-borne encephalitis vaccines licensed in Europe do not cross protect against Powassan virus infection.

ROCIO VIRAL ENCEPHALITIS

Rocio viral encephalitis should be considered in the differential diagnosis of viral encephalitis in endemic people or travelers from South America.

*References 4, 6, 7, 9, 11, 13, 14, 16, 17, 19-21, 23-25, 30, 34, 36, 37, 41, 42, 48, 49, 53.

Rocio encephalitis virus is a flavivirus and was isolated from the brain of a fatal case of encephalitis in a patient during an outbreak in 1975 in São Paulo State, Brazil.^{14,31} The virus is antigenically to viruses in the Japanese encephalitis virus complex. The disease has been reported exclusively in São Paulo State and adjacent Paraná State, Brazil, principally in the Ribiera Valley and Santista lowlands. More than 1000 cases were documented in outbreaks between 1975 and 1977; only one symptomatic case (in an infant) has been recognized subsequently, although recent infections (IgM in asymptomatic individuals) were documented in later serosurveys in northeastern and southeastern Brazil. Thus, the virus may be transmitted undetected in an area beyond the Ribiera Valley. Because of deforestation and global and geographic changes, as well as the competency of a wide variety of mosquito species for transmitting Rocio virus, it may emerge, like other previously obscure flaviviruses such as Zika virus, to become a more widely distributed pathogenic flavivirus. The viral transmission cycle has not been elucidated; however, field and laboratory observations suggest transmission between birds and *Psorophora* or *Aedes* mosquitoes. Seroprevalence studies in healthy Brazilian horses showed 6% were seropositive for Rocio virus, yet were entirely asymptomatic.⁴⁷ Humans are dead-end hosts. Human cases have occurred principally in men with outdoor occupations, especially fishermen.

The incubation period is estimated to be 7 to 14 days. Prodromal symptoms of fever, headache, malaise, vomiting, and conjunctivitis are followed by mental status changes, meningismus, and motor impairment. Cerebellar signs occur commonly. Signs of bulbar involvement also are seen. Coma and a fatal outcome occur most commonly in children (30%) and in older people; overall, 10% of cases are fatal, and 20% of patients have had neuropsychiatric sequelae. Pathologic findings of encephalitis principally involve the thalamus, cerebellar dentate nucleus, brain nuclei, brain stem, and spinal cord.

The diagnosis should be suspected in patients with acute encephalitis acquired in South America. The presence of virus-specific IgM in CSF or a fourfold change in serum antibody titer confirms a case, but cross reactions with St. Louis encephalitis, dengue, and other flaviviruses should be ruled out using virus specific PRNT serologic studies. There is no specific antiviral therapy effective for Rocio viral encephalitis, and treatment is therefore supportive.²⁹ Emergency application of adulticide and larvicide pesticides has been used to control epidemics.

LOUPING ILL VIRUS

Louping ill virus encephalitis should be considered in the differential of viral encephalitis in endemic individuals and travelers from the British Isles, especially in individuals with occupational or household exposure to sheep, cattle, and economically valuable game birds such as the red grouse.^{18,26} Louping ill virus derives its name from an old Scottish term describing the leaping motions of encephalitic sheep. Historical accounts of the disease in sheep date from 1795, and the virus was isolated in 1931. The virus is a member of the antigenic complex of tick-borne flaviviruses and is transmitted by *Ixodes ricinus* ticks.^{8,18,19,35} Sheep, deer, mountain hares, and grouse are the principal amplifying hosts. Grouse may become infected by tick bites or by ingesting infected ticks. The disease is enzootic in pasturelands of Scotland, England, Wales, and Ireland, where human infections have occurred mainly in sheep farmers, veterinarians, and slaughterhouse workers or butchers who had direct contact with animals or their meat. Antibody prevalence is 10% in slaughterhouse workers in enzootic areas. Laboratory-acquired infections are common and account for half of all reported human cases. These observations suggest that infections are transmitted easily by direct mucous membrane or respiratory infection. Hospital surveillance in an enzootic area found louping ill virus to be a rare occurrence that was responsible for fewer than 0.5% of encephalitis cases. Related tick-borne viruses in Spain, Greece, Norway, and Turkey have not been associated with human disease. The virus is shed in sheep and goat milk, but unlike tick-borne encephalitis, milk-transmitted cases have not been reported. Sheep in the United Kingdom are routinely vaccinated with a crude inactivated vaccine.

The incubation period can be as short as 3 days. Four distinct clinical syndromes have been described.⁸ These syndromes are influenza-like

illness, biphasic encephalitis illness, poliomyelitis-like illness, and hemorrhagic fever. Approximately a third of patients have a self-limited influenza-like illness with fever, headache, dizziness, and myalgias. The febrile illness is followed by clinical improvement and a second encephalitic phase in more than half of cases. Neurologic symptoms include meningismus, severe headache, vomiting, drowsiness, and tremor; one fatal case was reported. A poliomyelitis syndrome with muscle weakness or paralysis has been described in a few cases; the final presentation is hemorrhagic fever, which was reported in one atypical laboratory-acquired case.

The diagnosis should be suspected in febrile patients with occupational or other exposure, especially if central nervous system symptoms are present. The diagnosis can be confirmed by polymerase chain reaction or, serologically, by demonstrating virus-specific IgM in CSF or serum or by a fourfold rise in antibody titer. Treatment is symptomatic. Consumption of unpasteurized milk products should be avoided. Persons with outdoor exposure in enzootic areas are advised to use repellents and other protective measures against tick bites. Treatment of the disease is supportive, there is no specific antiviral therapy available for louping ill disease.^{15,29} Protective vaccination against louping ill virus infection in sheep is effective.²⁶ Licensed human vaccines against other tick-borne encephalitis virus are likely to be protective against louping ill virus infection, because of cross-protective antibodies.

KYASANUR FOREST DISEASE

Kyasanur Forest disease (KFD), also known as “monkey fever,” is a tick-borne arboviral fever in the Russian spring-summer encephalitis complex of flaviviruses. It infects humans with a severe biphasic course of illness, characterized by a hemorrhagic fever presentation in the first phase, and an encephalitis presentation in the second phase of illness, with an endemic geographical distribution in southern Karnataka, India.³ The disease is, however, emerging in other areas of India, despite surveillance and the availability of a vaccine. An outbreak occurred in 2016 in the Wayanad and Malappuram districts of Kerala, India, emphasizing that tick-borne diseases may emerge in new areas.⁴⁴ Exposure of the 2016 epidemic included indigenous tribes that depended on the forest for their livelihood and likely had high exposures to infected ticks in the forest.^{44,46} Kyasanur Forest virus was isolated in 1957 after an outbreak of hemorrhagic fever, initially suspected to be the first outbreak of yellow fever in Asia, appeared in India in the Kyasanur Forest of Mysore (now Karnataka).^{2,38-40} The virus subsequently was identified as a member of the tick-borne flaviviral antigenic complex and shown to be transmitted by *Haemaphysalis spinigera* (among numerous other ixodid ticks). Forest rodents, insectivores, and possibly bats, participate in the transmission cycle, and langur monkeys sicken in epizootics and die of the infection. Human cases occur in dry-season epidemics, chiefly in persons who have contact with tick-infested forests. The disease has spread geographically as villagers clear forests for pastureland. Between 1982 and 1988, 1847 cases were reported, 254 of which were fatal.³⁸ Hyperendemic transmission in Karnataka State continues despite the introduction of mass vaccination with a locally produced, inactivated chick embryo fibroblast-derived vaccine.³⁸ The geographic distribution of the virus is now known to be much broader, with virologic or serologic evidence of infection throughout China and on the Andaman and Nicobar Islands.⁵²

Additionally, a viral variant of the virus that has caused outbreaks of hemorrhagic fever in Saudi Arabia, Alkhurma virus, was transmitted to Italian tourists visiting the Egypt-Sudan border, indicating a distribution possibly encompassing a broad swath of Northern Africa, the Middle East, and into Central, South, and East Asia.^{6,34} Molecular epidemiologic studies support the ancestral eastward spread of tick-borne flaviviruses, possibly along camel trade routes or by migrating birds carrying infected ticks.²² Alkhurma virus has been acquired principally by persons who had close contact with livestock animals or their meat during or after slaughter, although mosquito-borne transmission from infected animals also has been suspected.³⁴ Tick-borne transmission was strongly suspected in the case of the Italian tourists.⁶

After an incubation period of 3 to 8 days, illness begins abruptly with fever, headache, myalgias, chills, and gastrointestinal symptoms.^{2,39,40}

Patients are seriously ill with facial hyperemia, conjunctival suffusion, lymphadenopathy, and hepatomegaly, and they may be bradycardic and hypotensive. A papulovesicular enanthem and petechiae are seen, and mucosal bleeding from the gums, epistaxis, hemoptysis, and gastrointestinal and vaginal bleeding may be prominent. Bronchopneumonia and hemorrhagic pulmonary edema complicate the illness in 40% of cases. Renal failure may develop. After the resolution of symptoms and an afebrile interval of 1 to 3 weeks, fever, recurrence of symptoms, and meningoencephalitis develop in 15% to 50% of cases, as occurs in tick-borne encephalitis. Although biphasic febrile illness also occurs in patients infected with Alkhumra virus, encephalitis, which complicates one fourth of cases, usually is a component of the primary illness.³⁴ Ocular findings may also occur. Leukopenia with a left shift, thrombocytopenia, and an elevated hematocrit reflecting hemoconcentration are seen, and, in some cases, evidence of disseminated intravascular coagulation. Elevations in liver enzymes are present in the majority of cases. The case-fatality rate is 3% to 15%. Keratitis and iritis have been reported to occur as sequelae. The virus frequently can be isolated from acute-phase blood specimens (<12 days after onset), or the diagnosis can be confirmed serologically. There is no specific antiviral treatment for tick-borne flavivirus infection associated with KFD, so treatment is supportive.^{15,29} Prevention is possible through an available vaccine with a formalin-inactivated tissue-culture vaccine available in India. Two doses administered 1 month apart confer temporary immunity for 6 to 12 months, and annual booster doses are recommended if outbreaks occur. However, because of vaccine side effects and the need for multiple doses and boosters, vaccine coverage is low, even in high-risk groups.²⁷

OMSK HEMORRHAGIC FEVER

Omsk hemorrhagic fever (OHF) virus was isolated from a viremic human during a series of outbreaks in the Omsk region of western Siberia, Russia, from 1945 to 1949.^{32,43} Omsk hemorrhagic fever is a tick-borne infection that occurs in the western Siberia regions of Omsk, Novosibirsk, Kurgan, and Tyumen. Between 1945 and 1958, approximately 1500 cases were reported in the forest-steppe zones within the Omsk, Novosibirsk, Kurgan, and Tyumen regions; however, the distribution of enzootic and human infections has shrunk considerably, and human cases now are reported sporadically only from Novosibirsk. The virus is related antigenically to other tick-borne flaviviruses and is spread by

Dermacentor marginatus, *D. reticulatus*, and *Ixodes persulcatus* ticks that may be dually infected with tick-borne encephalitis virus. Numerous small mammals, especially *Microtus* voles, are infected in the transmission cycle, but it was the introduction of muskrats (*Ondatra zibethicus*) into the region from Canada in the early 20th century that resulted in an expansion of viral transmission and large outbreaks in trappers, despite high mortality in the infected muskrats. Seasonal peaks of infection are in May to June and August to September, but recent cases, occurring principally among hunters and trappers, occur through the end of the year. Infections are transmitted by tick bites, directly from infected muskrats during skinning, and potentially from streams where the virus survives for months after being shed by infected animals. Alimentary infection from consumption of infected goat milk is possible but has not been reported. Laboratory-associated cases frequently have occurred.

The incubation period may be as brief as 2 to 4 days. The illness is similar to Kyasanur Forest disease from India and Alkhumra hemorrhagic fever from Saudi Arabia, but with an earlier onset of hemorrhagic phenomena (e.g., epistaxis). Hemorrhages tend to be less severe, and the overall mortality rate is lower (<3%). A second phase of illness develops after an asymptomatic period of 1 to 2 weeks in 30% to 50% of cases and frequently is dominated by neurologic symptoms and encephalitis. Laboratory diagnosis of OHF is by detection of the virus in blood samples by virus isolation or molecular techniques such as polymerase chain reaction (PCR) to detect the viral genome in blood or CSF during the acute first phase of illness. Treatment is supportive, and there is no specific antiviral therapy available for OHF.^{15,29} Antibody production may also be detected in serum and CSF later in the second phase of illness. Vaccine produced against tick-borne encephalitis virus is reported to provide some degree of cross protection for OHF.

OTHER FLAVIVIRAL INFECTIONS

Flaviviral infections of lesser public health importance or that are recognized less frequently are listed in Table 176I.1.^{1,5,33,36,54} Several of the viruses are known to cause human illness only after laboratory exposure, and others, such as Usutu virus, have been reported to cause illness only in highly immunocompromised patients.⁵¹ Alkhumra virus infection emerged in Saudi Arabia in 2001, as a serious zoonotic hemorrhagic fever, causing acute viral hemorrhagic fever in humans, and appeared to be transmitted from sheep or goats to humans by mosquito bites or direct contact with these animals.³⁴ The clinical

TABLE 176I.1 Less Commonly Recognized Flaviviral Infections

Virus	Clinical Syndrome	Geographic Distribution	Transmission Cycle	Mode of Transmission
Alfuy	Fever	Australia	Unknown	V

DC, Direct contact with infected sheep; E, experimental infection; L, laboratory-acquired infection; V, vector-borne infection; Z, zoonotic infection.

manifestations of these infections may differ from naturally acquired infection because of their mode of transmission by respiratory, mucosal, or other routes of infection. Other viruses that cause nonspecific syndromes of febrile illness were discovered through fever surveys; although few cases may have been reported, their prevalence may be underestimated because few cases are recognized.^{1,5,33,36,54} Because immune responses to repeated flaviviral infections lead to broadly cross-reactive responses, serologic diagnosis may be misleading unless extensive cross-neutralization assays are undertaken. Of the zoonotic flaviviruses (transmitted from animal to animal without an arthropod vector), only Rio Bravo and Modoc viruses are known to cause human illness.

Hepatitis C Virus

177

Ravi Jhaveri • Samer S. El-Kamary

Hepatitis C virus (HCV) is a major cause of chronic liver disease in both adults and children. HCV was officially discovered only 27 years ago, but progress in understanding the viral life cycle and developing therapies has been very rapid over the past decade. In the last few years alone, the rate of drug discovery has been breathtaking, with a major shift in HCV prognosis from a chronic and difficult-to-treat disease, to an illness that is readily curable using a combination of oral drugs. For children, the challenge will continue to be which patients require therapy and when is the right time to initiate treatment. This chapter attempts to summarize what is known about the HCV life cycle, how HCV presents in children, and how HCV treatment will change in the next decade.

HISTORY

After reliable testing for both hepatitis A and B was developed, it became clear that a significant number of bloodborne, transfusion-related cases of hepatitis existed. These patients appeared to be infected with an agent that tested negative for both hepatitis A and B and thus was deemed “non-A, non-B hepatitis.” The agent was suspected to be viral because transfer of blood from affected patients into naïve chimpanzees resulted in hepatitis. After a great deal of effort, the virus was finally identified in 1989.²⁶ A group at Chiron Corporation used molecular methods to identify RNA sequences from infected chimpanzees that were distinct from any known virus. HCV was the first pathogen to be described using only molecular methods, a practice that has now become the standard form of pathogen discovery. After a great deal of validation work, they named the virus hepatitis C virus.⁶⁸

VIROLOGY

HCV is classified in its own *Hepacivirus* genus within the Flaviviridae family.^{74,104} It is an enveloped, single-stranded, plus-sense RNA virus organized into one long open reading frame of approximately 9500 nucleotides.⁷⁵ It has the structural protein genes at its 5′ end and its nonstructural proteins toward the 3′ end.^{36,97} Fig. 177.1 illustrates how the HCV genome is organized and lists the names of individual proteins

and their main role during infection. The details of the molecular and structural biology of HCV are reviewed elsewhere,^{36,75,97} but several unique features of the HCV genome are worth noting here. The HCV RNA 5′ untranslated region (5′UTR) contains an internal ribosomal entry site (IRES), a feature that no other flavivirus contains.²⁸ The IRES allows for direct binding of host ribosomes to the viral RNA using a set of proteins different from those required for conventional capP-dependent translation. The 3′UTR does not feature a poly-A tail as many flaviviruses do.³⁶ The HCV E2 protein contains a hypervariable region that responds to immune-mediated pressure with hypermutation.³⁶ The viral RNA polymerase lacks proofreading ability and, with a replication rate of approximately 10⁸ virions per day,¹² has the potential to generate a mutation in every single position of the genome in one infected host every 24 hours. Whereas many of these are “lethal mutants” and do not survive, enough are generated that allow for one or more viable viruses that are able to rapidly escape antibody neutralization in a fashion very similar to that observed with human immunodeficiency virus (HIV). Each infected individual may harbor innumerable HCV variants that constitute a “quasispecies,” which often overwhelms the immune response and makes vaccine development highly complicated.^{50,51} The HCV NS3 is a multifunctional protein, with both helicase and protease domains.^{74,75} The HCV NS5A protein is an important cofactor for many viral processes, including RNA replication and viral assembly, and the HCV NS5B is the RNA-dependent RNA polymerase.^{74,75}

In vitro systems used to study HCV include subgenomic replicons, which are RNA constructs containing only the nonstructural region of the virus that can replicate themselves but produce no functional virus.^{16,76} Pseudoviruses using a retrovirus or Semliki Forest virus as a backbone have been used to study virus-receptor interaction.^{15,51} In 2005, a one-of-a-kind isolate of HCV was discovered in Japan, deemed “JFH1,” which was found to replicate in vitro and produce infectious virus in several liver cell lines.¹³² This discovery has since allowed for incredibly rapid progress in understanding the HCV viral life cycle.

HCV exists in the bloodstream in several different forms: naked virus, which would be the enveloped virus alone; HCV bound to antibody in higher density fractions; and HCV bound to low-density lipoproteins (LDL) and very-low-density lipoproteins (VLDL).^{6,9,10} These last two

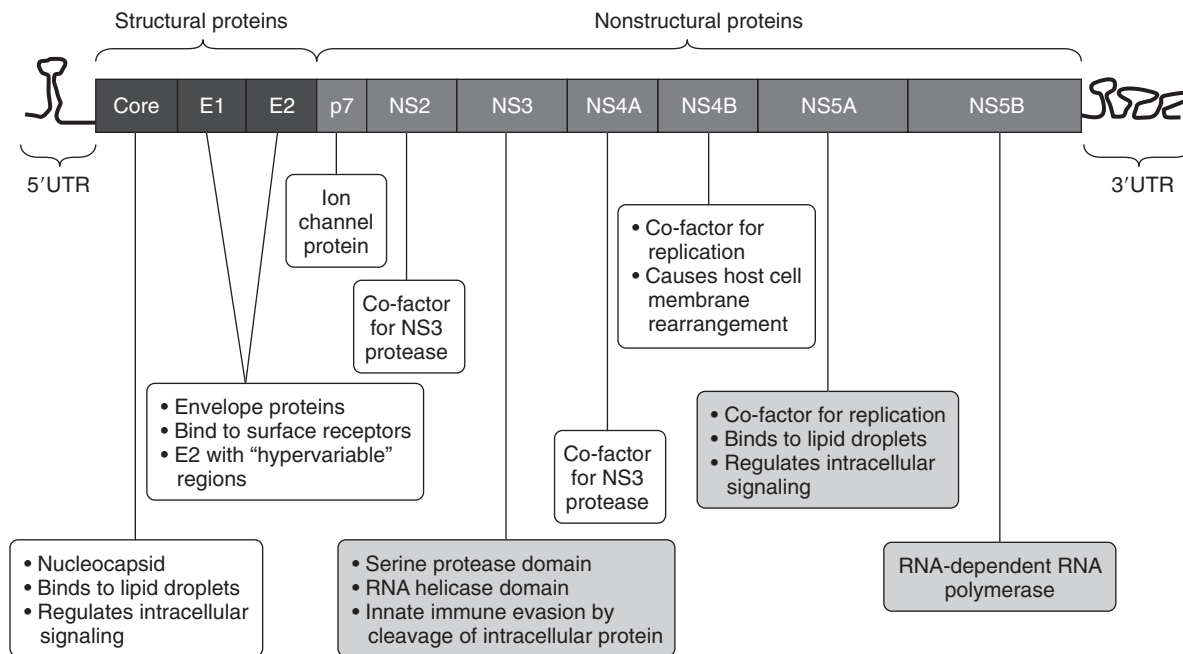

FIG. 177.1 Genomic organization of hepatitis C virus (HCV). HCV is organized as a single open reading frame coding for one polyprotein that is subsequently cleaved into multiple individual proteins. Structural proteins are shaded in *dark gray*, nonstructural proteins in *light gray*. The name and most important functions of each protein are provided. Proteins that are current or near-future direct antiviral targets are indicated by a *shaded* function box. *UTR*, Untranslated region.

fractions are deemed lipo-viro particles (LVPs) and have been shown to be the most infectious form of HCV.^{6,10,14,41}

PATHOGENESIS

After gaining access to the bloodstream, the virus enters the liver through the sinusoidal blood, after which viral cell entry is a complex multistep process, requiring several cellular factors that trigger virus uptake into the hepatocytes. The virus replicates within the infected cell but does not cause cytolysis.^{74,75} HCV replicates to very high levels within liver cells, and a significant proportion of the virus is released into the bloodstream. The exact levels of virus in the liver vary considerably from patient to patient based on age, genetics, and other host factors, with the interaction between virus, host liver cells, and host immune cells resulting in either resolution of infection or progression to chronic infection.^{25,29} Resolved acute HCV has no long-term consequences. During chronic infection, inflammatory signals are released from the infected cells that, over time, contribute to the fibrosis and necrosis that is observed with long-standing infection.¹¹⁴

VIRAL LIFE CYCLE

HCV has been shown to interact with several proteins that serve as primary receptors or coreceptors depending on whether it is the initial infection or whether cell-to-cell spread has occurred within an already infected liver.⁹⁹ Viral entry occurs in three main steps, by poorly understood mechanisms: (1) viral attachment to the hepatocyte; (2) receptor-mediated viral particle endocytosis; and (3) endosomal fusion.¹⁴¹ The first interaction appears to be when LVPs interact with the scavenger-receptor B1 (SR-B1) protein.²¹ This interaction is not required, and other lipid-related proteins such as the low-density lipoprotein receptor (LDLR) may substitute for SR-B1.⁸⁷ Given the enrichment of these proteins on liver cells, this step likely provides much of the tissue specificity for the virus. After this initial binding step, a more specific interaction takes place between the HCV E2 protein and the CD81 molecule.^{62,140} This interaction is thought to be a critical one for initial

infections. This E2-CD81 complex then traffics to the tight junction of the cell, where interactions with both tight junction proteins claudin-1 and occludin-1 mediate the final steps in viral entry.^{34,47,100} It has been shown that for direct cell-to-cell spread, the tight junction proteins can mediate infection alone, bypassing the need for CD81 or SR-B1.¹²⁶ After cell entry, HCV relies on a specific interaction with a liver-specific microRNA, miR-122, as a necessary cofactor.⁶⁰ The HCV RNA has two sites in the 5'UTR that are complementary to miR-122.⁵⁹ This is the first instance of a microRNA enhancing the function of an RNA, because in almost every other circumstance, microRNAs serve to silence gene expression by causing degradation of mRNA.

Another key step in the HCV life cycle is the association of the core protein with lipid droplets as part of viral assembly and release.^{18,85} When first discovered, this was unique among flaviviruses, although it is now understood that dengue virus also associates with lipid droplets.¹¹⁰ When bound to lipid droplets, the core protein recruits other viral proteins and newly synthesized RNA to form new virions.⁸⁵ Disruption of this association prevents the release of infectious virus.¹⁸ HCV has evolved to co-opt many host lipid synthesis and trafficking pathways—binding to lipid droplets, requiring several apolipoproteins for assembly, and using VLDL export pathways for viral release.^{10,14,54,63,85,109,115,117}

EPIDEMIOLOGY

The epidemiology of HCV varies significantly based on age and geography. In the general US population, approximately 4 million have HCV antibody-positive status and approximately two thirds of those have chronic infection.^{8,12} In children, between 0.1% and 0.4% have evidence of HCV antibody.^{8,32} In recent years, cases of HCV have been rising in teenagers and young adults due to widespread opioid abuse.¹⁴²

Certain countries are known to have exceedingly high rates of HCV seroprevalence, largely as a result of unsafe injection practices and a contaminated blood supply. Pakistan is known to have HCV seroprevalence rates of 4% to 10%.^{65,129} In Egypt, 10% to 15% of the general population, including children, have HCV antibody-positive status.^{46,61,116}

This the highest rate in the world and is largely due to widespread inoculation of many individuals during a 20-year public health intervention to control schistosomiasis.^{37,40} After screening for the parasite in the stool and urine, patients were treated with an intravenous tartar preparation.¹¹⁹ While this was a well-intentioned public health intervention by the Ministry of Health, there were no disposable syringes available and, unknown to them at the time, boiling of glass syringes and needles in water was not sufficient to kill the virus. Once oral praziquantel replaced the intravenous treatment, the rates of HCV infection from this intervention were reduced significantly. However, the seroprevalence in the population was already high, and other modes of transmission serve to perpetuate the epidemic.^{2,33,86,98}

VIRAL GENETICS

HCV has six major genotypes of HCV that vary in their geographic distribution.^{36,84,118} Genotypes 1a and 1b are the most prevalent genotypes in the United States and Western Europe. Genotypes 2 and 3 are minority genotypes in this region, but are more frequently observed in Asia and Australia. Genotype 4 is frequently observed in Africa, particularly in Egypt. Genotypes 5 and 6 are minority genotypes, mostly in Africa.

The different genotypes are associated with important clinical phenotypes. Response to interferon (IFN)-based therapy varies widely based on genotype.³⁹ Genotypes 2 and 3 are exceedingly responsive to IFN, with sustained response rates between 80% and 90%. Genotypes 1a, 1b, and 4 all respond to IFN at much lower rates, closer to 40% to 50%. Genotype 3 is associated with more frequent and more severe steatosis (fatty liver) in contrast to other genotypes.^{53,95}

TRANSMISSION

HCV is transmitted efficiently by exposure to blood and blood-containing solutions, tissue, and equipment.^{74,139} Before the advent of effective tests for screening blood and blood products in the early 1990s, virtually all patients dependent on regular transfusions, such as hemophiliacs and patients with hemoglobinopathies, became chronically infected with HCV.^{7,134} In the current era, in which blood supplies are rigorously screened, the primary route of blood-borne transmission is among injection drug users. Nosocomial transmission from medical and dental equipment is a constant issue that manifests when intentional and unintentional breaches of sterile techniques occur.^{4,48,22,105,122}

For children, the major route of transmission is mother to infant (vertical transmission).¹³ It is clear that only mothers with active viremia will transmit HCV, but beyond that, no clear risk factors for transmission have been defined.^{131,79,103,116} Although higher viral loads increase risk, no threshold level has been defined. Cesarean section has not been demonstrated to be protective against transmission.^{31,22,79,83} Studies from countries with different prevailing genotypes demonstrate comparable rates of transmission.^{131,79,116} Overall transmission rates vary between 5% and 10%, depending on the study. In the era before highly active antiretroviral therapy (HAART), HIV coinfection raised the vertical transmission rate to 20% to 25%.^{92,103,125} However, in the current HAART era, if a woman's HIV disease is suppressed or well controlled, the risk for HCV vertical transmission is comparable to that with HCV monoinfection.²³ For reasons that are not entirely clear, a significant rate of spontaneous resolution of HCV infection occurs among young children such that up to 50% of those with an initial transmission resolve their HCV viremia, leaving a rate of chronic infection after vertical transmission of 3% to 5%.^{22,116}

Other, less frequent modes of transmission deserve some discussion. Sexual transmission is an inefficient and uncommon route of transmission.^{78,89,123} This has been demonstrated largely in long-term studies of serodiscordant couples, in whom the infection rate was only 1% to 2%, and many of those who seroconverted had independent risk factors for HCV infection. The exception to this is for men who have sex with men, which is a high-risk exposure.⁶⁹ Tattooing is not considered a high-risk exposure, particularly in the current era when sterile techniques are commonplace.¹²⁷ This may not be true for a war veteran or prisoner, or community "tattoo parties" where sterile techniques may not be used. Breast-feeding has never been documented as a source of infection

and is not contraindicated in new mothers who have HCV infection.^{31,67,72} Other microscopic blood exposures from razors and toothbrushes are possible and are targets for prevention measures.¹³¹ In a fraction of patients, no obvious risk factor for HCV exists. It is presumed that some of these microscopic exposures may have been the cause in these cases or that patients either may not recall their high-risk exposure or may not be entirely forthcoming.

CLINICAL MANIFESTATIONS

HCV in most cases is an asymptomatic infection.^{7,58} Patients are often diagnosed when seeking medical attention for other reasons and are found to have elevated liver enzymes. In the minority of cases, patients will have acute signs of hepatitis, including malaise, jaundice, abdominal pain, and discomfort.¹³³ This is often the sign of a robust immune response that may portend clearance of the acute infection. In most patients, there are no acute symptoms and the infection quietly progresses from acute to chronic over the course of several months.

For children infected with HCV, these same observations largely hold true.⁵⁸ Infants infected at birth manifest no symptoms for many years.¹²⁸ They are often diagnosed only because the mother is known to be infected or has several high-risk factors that warrant screening. Some infants may have elevated transaminases early in life, but most do not. HCV does not alter physical growth or cognitive development. This is an important point to emphasize with parents in counseling during early visits.

Children are also frequently diagnosed during their teenage years during screening for other reasons. Commonly encountered scenarios include testing of those who were preterm infants born in the late 1980s or early 1990s, especially those who needed blood transfusions, or teenagers who were screened as part of a school blood donation drive and tested positive for HCV antibody.

The major risk for chronic HCV infection is the progression to chronic liver disease, which includes both cirrhosis and subsequent hepatocellular carcinoma (HCC).¹¹⁴ The rate of these complications in children is low, approximately 5% of the time, but it increases with duration of infection. A European study demonstrated that cirrhosis was observed only in children infected for more than 10 years.⁵⁷ A large US study demonstrated that many infected children who underwent biopsy had either mild or no fibrosis.⁴⁵ Teenagers can have HCV-associated cirrhosis or HCC requiring transplant.¹⁰⁸

HCV has a variety of extrahepatic manifestations that are primarily observed in adults, but may be possible in children.^{20,55} These are skin and joint manifestations such as porphyria cutanea tarda, mixed cryoglobulinemia, and vasculitis that are due to immune complex deposition in small vessels. HCV has also been associated with insulin resistance and resulting diabetes.⁹¹ Although the specific mechanism of this is unknown, it is likely due to effects of the HCV core protein on regulation of glucose metabolism at multiple levels within liver cells.^{90,96} HCV also has been associated with extreme levels of fatigue and altered mood and concentration.¹¹¹ It has recently been demonstrated that HCV can infect brain endothelial cells in vitro, and immunohistochemistry has shown HCV to be present in the brain tissue of chronically infected patients.³⁵ This raises the possibility that HCV may have some direct effect on the brain.

IMMUNITY

HCV infection is associated with both a cellular and humoral immune response.¹⁹ Responses can be detected after approximately 6 to 8 weeks of infection. Patients with acute infection have evidence of a robust cell-mediated response, with readily detected HCV-specific CD8⁺ T cells.¹³³ This response mediates clearance of acute infection in these patients. Most patients, however, have specific T cells detected, but the response is weak and ineffective. These patients progress to chronic infection, and over time their T cells display an exhausted phenotype that has little impact on the course of infection.¹⁰²

HCV antibodies are detectable throughout the course of infection, but their role in preventing infection is unclear.¹⁹ As mentioned earlier, neutralizing antibodies to HCV are not observed because of the

hypermutation observed in the HCV E2 protein generating many “quasispecies” of HCV that escape neutralization. However, the presence of antibody may alter progression of infection over time in ways not yet understood. HCV also interacts with the innate immune system to subvert host response to viral infection.⁴⁹ Multiple proteins have been demonstrated to directly cleave IFN-induced mediators of host protection.¹²¹ A more specific discussion of these effects can be found in several in-depth reviews.^{40,49}

DIAGNOSIS

HCV infection can be diagnosed by demonstration of HCV-specific antibody, the presence of HCV RNA from serum or blood samples, or direct demonstration of HCV proteins in serum or blood samples.⁵⁶ First-pass screening of at-risk children is usually done with enzyme-linked immunosorbent assay (ELISA)-based testing. If positive, patients can be tested using a highly specific recombinant immunoblot assay, which detects the presence of antibodies to several HCV proteins. However, this is very rarely necessary. Most practitioners would move immediately to testing for HCV RNA, because the presence of RNA demonstrates chronic infection, which is the most important biomarker of infection. HCV RNA is now done using a real-time polymerase chain reaction (PCR)-based assay that offers the advantages of both reliability for presence of viral RNA and a broad dynamic range for quantitation.²⁴ If HCV RNA is detected, a frequent next step is determination of HCV genotype, which is done by characterizing the sequence of the HCV polymerase gene.¹¹⁸ As has been discussed previously, knowledge of genotype can have a major impact on the choice of how and when to treat a patient. Liver biopsy is now rarely performed in favor of noninvasive methods of fibrosis assessment. An algorithm for the evaluation of a child with HCV-positive antibody testing is outlined in Fig. 177.2.

The testing of those infants who are vertically exposed is an altogether different matter. Because of the persistence of maternal antibody and the significant potential for spontaneous resolution of infection in young children, simple ELISA or single-point HCV RNA can be misleading.^{131,116} There is no consensus on the best time to test these infants. The approach of this author is outlined in Fig. 177.3. Because no treatment is initiated during infancy, testing is not recommended in the first year. The possible exception to this is if a parent has considerable anxiety over the possibility of infection or if there is a concern about possible loss of follow-up. In that case, performing an HCV RNA test in the first 2 to 6 months of life can be considered. If the test is negative, it is very reassuring, although not absolute that the child is not infected. A positive result indicates infection but still leaves open the possibility that the infant may spontaneously resolve the infection over the next 1 to 2 years. Preferred timing for testing would be after the first birthday and should include both an HCV antibody and HCV RNA PCR. A repeat result several months later confirming a negative test should be performed before declaring a child uninfected. If the initial test result is positive, a repeat in 6 to 12 months should be performed, and, if the result is still positive, an annual monitoring plan that includes a careful history and physical, liver function testing, and HCV RNA testing should be initiated.

Assessment for Severity of Disease

In addition to a careful physical examination to determine if signs of chronic liver disease are present, assessment of laboratory, radiologic, and pathologic specimens should be performed. The severity of transaminase elevation, if any, should be determined. These tests are notoriously insensitive for disease of mild and moderate severity but are helpful when normal or significantly elevated.¹⁰¹ Other laboratory tests should be performed to assess the synthetic function of the liver (albumin, prothrombin time, partial thromboplastin time, etc.).⁷⁷

Routine radiologic studies are not necessary for all HCV-infected patients. Ultrasound of the liver can be used at an initial visit for an assessment of any anatomic factors that may complicate future assessments.⁷⁷ Unlike hepatitis B virus, with which the risk for HCC is independent of liver damage, with rare exception, HCC with HCV occurs only after cirrhosis is present.⁵² If a patient is known to have HCV-induced cirrhosis, annual ultrasounds are justified. If not, periodic testing every 5 years or so may be more appropriate.

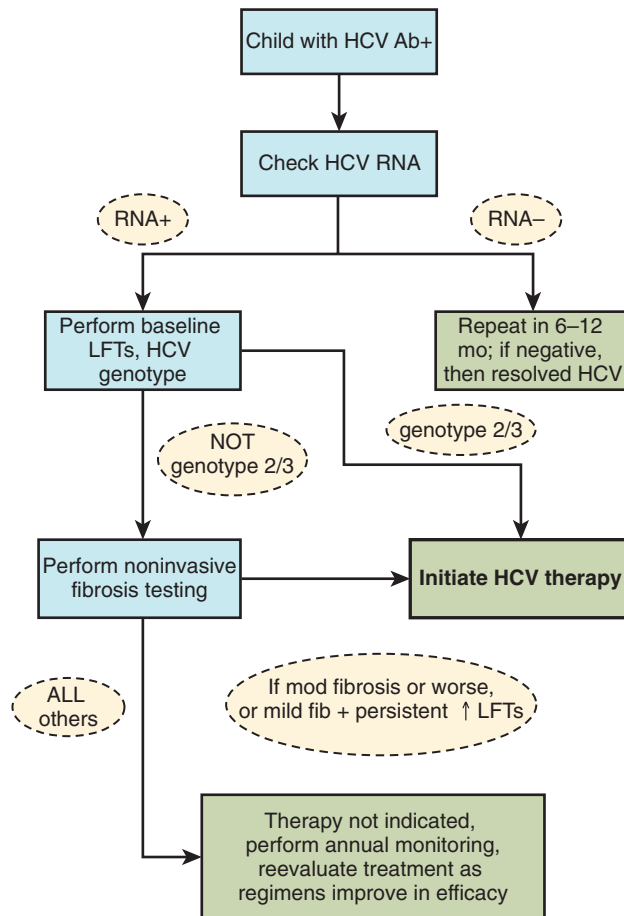

FIG. 177.2 Suggested algorithm for evaluation of a child with evidence of hepatitis C virus (HCV) antibody. Endpoints are highlighted by a shaded box, while key result branch points in the decision tree are highlighted in the ovals with dashed borders. Ab+, Positive for antibodies; LFTs, liver function tests.

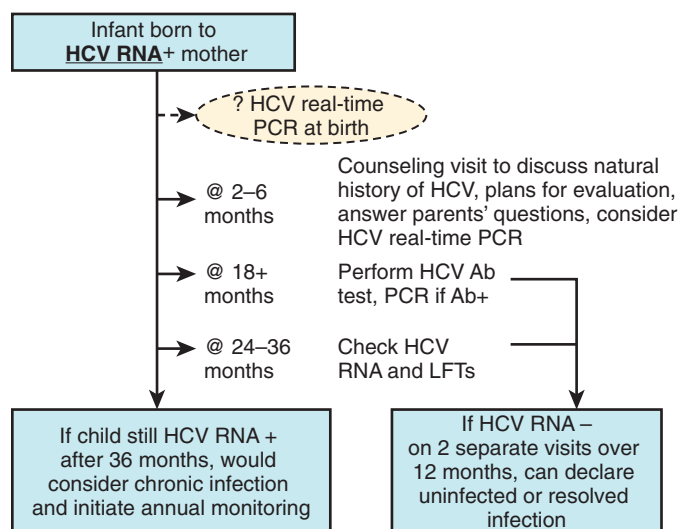

FIG. 177.3 Suggested algorithm for evaluation of the infant vertically exposed to hepatitis C virus (HCV). Endpoints are highlighted by a shaded box, while testing that has not yet been studied are highlighted with dashed borders. Ab, Antibody; LFTs, liver function tests; PCR, polymerase chain reaction.

Definitive assessment of HCV-induced liver damage is done using a liver biopsy, but this is rarely performed in the current era unless there is concern for other causes of liver disease.⁷⁷ More recently, sensitive ultrasound-based methods have been approved that are used to evaluate liver stiffness and fibrosis.^{30,94} These are now being increasingly used to follow liver fibrosis and cirrhosis in HCV-infected adults and children

in lieu of liver biopsy. Many studies have been performed to determine if combinations of laboratory or radiologic tests can be used to assess for liver fibrosis in the absence of a liver biopsy. These so-called non-invasive markers of fibrosis consist of a variety of blood tests that are used to create a score or index that allows for subsequent selection of those more likely to have severe liver damage. Most of these tests perform reasonably well at the ends of the disease severity spectrum, but very poorly in the middle.⁹³ This is true in children as well.⁸⁰

Host Genetics

Studies performed in the past several years have now demonstrated that host genetics plays a significant role in the course of HCV disease. As part of a genome-wide associated study, polymorphisms within the *IL28b* gene were initially shown to have an exceedingly high correlation to response to treatment with IFN-based therapy.⁴² In examination of the rates of the favorable polymorphisms in different ethnic groups, these polymorphisms potentially accounted for most of the racial and ethnic differences seen using IFN-based therapy. Further studies demonstrated that these polymorphisms also correlated very highly with patients resolving acute HCV in contrast to those whose disease progressed to chronic infection.¹²⁴ The mechanism underlying these significant differences has yet to be determined, but because *IL28b* encodes for a lambda-IFN that then regulates subsequent host antiviral responses, studies are being conducted to closely examine the initial lambda-IFN dynamics. No studies have thus far been performed in children, but because these are genetic differences, they likely will have the same impact there. One study searched for a potential role of this polymorphism in predicting and determining vertical transmission, but no correlation was found.¹⁰⁷ It is important to emphasize that although this polymorphism on a population level is an exceedingly powerful predictor of HCV clearance and response to therapy, it is still unclear how to use this information for the individual patient. Although this polymorphism is not absolutely predictive of response, it was used as a general guide for counseling patients in the era of interferon-based therapy.²⁷

However, with the advent of oral direct-acting antiviral therapies that are not affected by the patient's IL28B status, it is no longer taken into consideration when planning an adult patient's therapeutic regimen.¹ A similar management approach is expected for children once these therapies are approved for younger age groups.

TREATMENT

The issue of when to initiate therapy for a child infected with HCV is still under contention.⁷⁷ There is no controversy in the case of a child who has clear evidence of liver compromise from long-standing HCV infection, but these cases are the minority. Because natural history studies of children with HCV do indicate that many of them will do well with only minimal progression of liver fibrosis, treatment initiation remains a controversial issue. Proponents of therapy argue the many potential benefits of treating children: the cost advantage of using less of an expensive drug when treating a smaller person; the number of years of "virus-free" life still ahead for a child; the absence of comorbidities in a child that may complicate treatment; eradicating virus before entering adolescence, when high-risk behavior that can potentially transmit the virus traditionally begins; and for girls, eliminating the potential for vertical transmission. At this point, the decision about when to treat is one that should be individualized on a case-by-case basis.

HCV treatment recommendations are rapidly changing, so the AASLD/IDSA have partnered to form a guidelines panel to maintain an up-to-date website with the most current information that now includes children.¹ The reader is referred there for a detailed discussion of drug doses, adjustments, and side effects. HCV therapy is undergoing a significant transition as more agents against specific viral proteins emerge from preclinical studies. This section attempts to cover currently approved information for HCV as well as what is anticipated in the next several years. Specific attention is focused on the existing data for treating children. The goal of HCV treatment is the eradication from the bloodstream of viral RNA that persists after the discontinuation of therapy. This is in stark contrast to HIV therapy, which is suppressive only while the medications are continued. It is thought that treatment for HCV reduces the burden of virus in the liver such that either HCV is completely eradicated

from the system or the immune system is able to control the virus to such low levels as to be undetectable in the bloodstream. Rare cases have been reported of viral reemergence long after treatment response when immunosuppression is initiated for an unrelated reason, supporting the latter as a likely scenario.⁷³ For interferon-based therapy, the endpoint of HCV therapy is the sustained viral response (SVR), which was defined as the absence of detectable HCV RNA at 6 months after completion of therapy.^{39,82} However, in the current era of direct-acting antiviral (DAA) therapy in adults, SVR is now defined as the absence of HCV RNA at 12 weeks after completion of therapy¹ and will presumably be the same after the new therapies are approved for children younger than 18 years of age. If patients do not achieve SVR, they are categorized as nonresponders (i.e., patients who never suppressed virus during treatment), partial responders (i.e., patients who partially suppressed virus early but then had recrudescence), or relapsers (i.e., patients who completely suppressed virus for some amount of time but then had recrudescence at some point later). Knowledge of this terminology is helpful in interpreting the HCV treatment literature and important because each group has a different prognosis if new treatment regimens are attempted later.

IFN- α and its chemically modified derivatives have long been the backbone for HCV therapy. Old preparations given subcutaneously three times per week offered SVR rates of only 15% to 20%.²⁹ In an attempt to improve the poor pharmacokinetics of traditional IFN, a polyethylene glycol (PEG-IFN) moiety was added to allow for much higher serum concentrations combined with less frequent weekly subcutaneous dosing. The use of PEG-IFN improved SVR rates by almost 20%.³⁹ It is interesting to note that studies examining patients with the favorable and unfavorable IL28b polymorphisms have shown that HCV patients who achieve SVR are those with low levels of IFN-induced gene expression that are readily enhanced with IFN administration, whereas patients who do not respond to treatment have high IFN-induced gene expression that is ineffective in counteracting the virus and incapable of being augmented with exogenous IFN.^{3,130} It has long been known that significant racial and ethnic differences exist in rates of response to IFN therapy. African-American and Hispanic/Latino patients achieve SVR at rates significantly lower than those of Caucasian or Asian patients.^{82,88} Much of this may be due to differences in IL28b status, but not entirely.

Ribavirin was mainstay of HCV therapy in children and can still be used in combination for certain genotypes. When traditional IFN was still being used with very low SVR rates, other agents were sought to boost its effects. With the addition of orally administered ribavirin, SVR rates increased to almost 40% for patients infected with genotypes 1a or 1b.⁸¹ When PEG-IFN was developed, the combination of PEG-IFN and ribavirin resulted in SVR rates of 40% to 50% for genotype 1a and 1b patients and 80 to 90 for genotype 2 and 3 patients.³⁹ The mechanism of action of ribavirin is still unknown, but it is thought to inhibit viral replication efficiency enough to make the virus more susceptible to other agents. Ribavirin monotherapy has no effect on HCV RNA levels and does not lead to SVR.¹⁷

Although no longer the standard of care, PEG-IFN and ribavirin have been studied and approved for use in children at reduced doses.^{56,112,113,135} Small pharmacokinetic studies determined that dosing of PEG-IFN based on either weight or body surface area led to serum drug levels comparable to those in adult administration.¹¹³ Ribavirin is given on a weight-based dose for both children and adults.⁴⁴ The largest single study of HCV treatment in children was the Pediatric Study of Hepatitis C (PEDS-C) trial, which compared PEG-IFN alone to PEG-IFN plus ribavirin.¹¹² The rationale for this design was that many thought that PEG-IFN alone may be sufficient in younger children with the absence of many other adverse risk factors. The PEDS-C trial demonstrated that children had overall SVR rates comparable to their adult counterparts (53%) when treated with both drugs, significantly better in contrast to when PEG-IFN was used alone (37%). Several factors must be considered when treating children with these agents.^{77,112} Side effects of PEG-IFN include flulike symptoms and malaise. For children attending school who require maximal function during the school week, PEG-IFN administration on Friday with coadministration of a nonsteroidal antiinflammatory agent has been effective in alleviating these effects. IFN can also cause neutropenia and hemolytic anemia, both of which can be managed with dose reduction. PEG-IFN has been shown to cause depression and suicidal ideation, dangerous at any age but particularly worrisome during the usually emotionally turbulent

adolescent years. A side effect unique to children is the associated arrest of linear growth during PEG-IFN treatment. Although children do experience catch-up growth once the drug is discontinued, long-term follow-up is still being conducted to determine whether children actually attain their predicted midparental height.⁶⁴

Starting in 2009, several directly acting antiviral drugs were approved by the FDA for adults. In 2009, two oral protease inhibitors were approved, boceprevir and telaprevir, which when combined with pegylated interferon and ribavirin increased the cure rate to 70% to 75% but had increased side-effects.^{10,50,94,128} Two additional oral drugs were approved by the FDA in 2013, sofosbuvir (nucleotide analogue NS5B polymerase inhibitor) and simeprevir (protease inhibitor) which improved the cure rate to 90% when individually combined with pegylated interferon and ribavirin.^{38,66} In July 2014, the first all-oral HCV-treatment regimen without interferon or ribavirin was approved by the FDA: a combination of ledipasvir (NS5A inhibitor) and sofosbuvir.⁵ Later in 2014 (November), simeprevir and sofosbuvir were approved as another interferon-free all-oral treatment.⁷¹ In December 2014, another all-oral regimen consisting of a combination of four drugs was approved by the FDA: ombitasvir (NS5A inhibitor), paritaprevir (NS3/4A protease inhibitor), ritonavir (CYP3A inhibitor), and dasabuvir (nonnucleoside NS5B polymerase inhibitor).¹¹ In 2015, another oral medication was approved, daclatasvir (NS5A inhibitor), for use with sofosbuvir to treat HCV genotype 3 infections without the need for coadministration of interferon or ribavirin.¹²⁰ In January 2016, the FDA approved elbasvir (NS5A replication complex inhibitor) and grazoprevir (NS3/4A protease inhibitor) with or without ribavirin for the treatment of chronic HCV genotypes 1 and 4 infections in adult patients.^{70,106} In April 2017, sofosbuvir/ledipasvir was approved for use in children ages 12 to 17 years.¹⁴³ Clinical trials are currently ongoing with several DAA regimens in children down to 3 years of age.¹³⁶⁻¹³⁸

What also becomes possible in the future is interruption of vertical transmission using these specific antiviral agents in and around the time of delivery in a manner similar to treatment of HIV.¹³ Given the much lower risk for transmission and lower morbidity and mortality in contrast to HIV, further studies into understanding better which mothers transmit HCV and when they transmit the virus would allow more selective drug use.

PREVENTION AND COUNSELING

No specific prevention measures are currently available against HCV infection. Attempts to create a vaccine have been frustrated by the heterogeneity of the virus and an incomplete understanding of immune correlates of protection that can reliably predict protection against the virus. Prevention largely rests on avoiding high-risk behaviors, rigorous sterile technique to avoid nosocomial transmission, and screening to identify HCV-infected adults and children so patients can be evaluated and treated. Counsel for the child who is already infected with HCV should include prompt care of bloody injuries, vaccination against other forms of viral hepatitis (hepatitis A and B) to avoid potentiated injury to the liver, being aware of prescription and nonprescription drugs that cause liver toxicity, and being aware of the risks of alcohol use when chronically infected with HCV and that no known safe level of alcohol consumption exists for HCV-infected patients.⁷⁷ It is also important to reiterate to parents that HCV-infected children grow and develop normally and do not present a risk to classmates. It is also important to advocate for HCV-infected children because some schools and other agencies needlessly continue to try to restrict the attendance and activities of HCV-infected children.

SUMMARY

Children with HCV infection often do very well with few or no long-term effects, but a few children do develop significant liver disease. A working knowledge of how to monitor and manage these patients can assist in mitigating the severity of disease. The treatment of HCV is in the midst of major changes that will revolutionize the field. Although multiple new oral anti-HCV direct-acting antiviral agents have been approved in adults,¹⁴³ they are still not ready to be used for children. Nevertheless, familiarity with what will ultimately become available will assist providers in discussions with their patients.

Influenza is an acute respiratory disease caused by influenza viruses. Children are the main amplifiers of the virus, because of their naïve immune systems, and the main vectors for transmission, because of their high social contact rate. The clinical attack rate and hospitalization rate are also highest in young children. Evolutionarily, all influenza viruses are zoonoses, arising in the animal reservoir and spilling over into the human population. Children are often the first hosts in which infections are detected following cross-species transmission events, which are typically with swine or avian influenza A viruses. Several times a century, one of these zoonotic events results in a new influenza virus lineage becoming established in humans and circulating for years or decades as an endemic strain. The worldwide pandemic that occurs shortly after the nascent virus becomes established can have a profound impact on morbidity and mortality in children and young adults, with high rates of severe disease requiring intensive care and a higher case fatality rate in children than is typical with seasonal influenza. Because influenza viruses continually evolve and the illness they engender can vary considerably based on characteristics of the strain, the weather, and other circulating or endemic pathogens, as well as the number of susceptible hosts, the impact of each season on human health is unpredictable. To remain abreast of the latest information, clinicians are therefore referred to sources such as the Centers for Disease Control and Prevention (CDC)⁵⁸ and the World Health Organization (WHO)⁵⁰³ for updated guidance on epidemiology, treatment, prevention, and control of influenza.

HISTORY

The origin of the term influenza has several possible derivations; the most likely is from the Latin *influentia* in the astrological sense of believing the stars have influence on disease. The first application of the word influenza to actual influenzal disease was probably during the 1743 pandemic, which started in Italy and spread worldwide,¹⁵ but the term had been used since at least 1357 to describe various disease outbreaks, some of which were clearly not influenza.¹⁹² Descriptions of epidemic respiratory disease that were likely to be influenza date back to as early as 412 BCE in an account by Hippocrates.¹⁹² Numerous accounts of similar outbreaks can be found throughout the next two millennia.⁴⁴⁰ The first description of an outbreak from multiple continents widespread enough to represent a pandemic occurred in 1580. Sporadic observations from autopsies document likely secondary bacterial pneumonia associated with an influenza epidemic as far back as the early 1700s.³²⁸ René T.H. Laennec, the inventor of the stethoscope and the technique of auscultation, was the first to fully appreciate this association between epidemic influenza and bacterial pneumonia. During an 1803 epidemic of “la grippe” in Paris, he described several autopsies on patients who developed fatal lobar pneumonia shortly after an influenza-like illness.²⁴⁹ This association of secondary bacterial infections with mortality came into sharper focus during the 1918 pandemic, which killed an estimated 50 million persons worldwide. More than 95% of all deaths from the 1918 influenza virus were associated with a secondary bacterial infection³²⁹; Louis Cruveilhier succinctly summed this up with the phrase, “if grippe condemns, the secondary infections execute.”⁸⁵ The first influenza virus isolate came from an experimental infection of swine by Richard Shope in 1930.⁴¹¹ Pigs only exhibited disease from *Haemophilus influenzae suis* when they were coinfectd with a second agent, which turned out to be swine influenza virus upon isolation.^{411,412} The first human isolation was in 1933 when scientist Wilson Smith, working with experimental infection models in ferrets,

contracted influenza from one of the animals and developed secondary pneumococcal pneumonia.¹² Identification of influenza B viruses followed in 1936.¹²² The discovery of the wild bird reservoir of influenza did not occur until the early 1970s when avian influenza viruses were isolated from wild birds,⁴¹⁹ allowing the ecology of these viruses to be elucidated through a series of field studies.⁴⁸⁰

BIOLOGY

Properties and Life Cycle

The hemagglutinin (HA) of influenza A and B viruses is the primary attachment protein. Structurally, the HA is a glycoprotein that exists in the virus as a trimer, with a globular head positioned as a spike through the captured cell membrane, and a fusion domain that protrudes through the membrane toward the virus's protein shell.^{128,490} The nascent HA (termed HA0) must be proteolytically activated through a cleavage step mediated by a furin-like protease, resulting in HA1 and HA2 subunits that are capable of significant structural changes during membrane fusion.^{38,128} Binding of the HA's evolutionarily conserved receptor binding domain to cell surface sialic acids allows internalization of virions by endocytosis into the acidic endosome (Fig. 178.1). The M2 protein, which is an ion channel spanning the virus's captured cell membrane, then acidifies the interior of the virion, triggering HA-mediated fusion of the virus envelope with the endosome through a “spring-action” extension of the fusion domain through the membranes that results in merging of these membranes and creation of an opening between the cytoplasm and the virion interior.^{49,133} This merger allows release of viral ribonucleic acids and the proteins that make up the RNA polymerase complex (PB2, PB1, and PA) into the cytoplasm.

The vRNAs and polymerase complex proteins move to the nucleus, where transcription of (–) sense gene segments using a (+) strand copy-RNA intermediate (cRNA) takes place, together with production of (+) sense mRNAs.^{238,406} Nascent (–) strand viral RNAs (vRNAs) are incorporated with NP into vRNPs and exported from the nucleus via the nuclear export protein NS-2 and the matrix protein 1 (M1).⁹⁶ mRNA leave the nucleus and act as template for synthesis of accessory, structural, and glycoproteins. Structural proteins, primarily M1, congregate at the cell membrane, initiating assembly and preparing for budding.³²⁷ The glycoproteins, HA and the neuraminidase (NA), are shunted through the endoplasmic reticulum (ER) and Golgi network for folding and posttranslational modification, including addition of glycans, prior to shuttling to the assembly site where they are inserted into the cell membrane.^{88,386,407} Budding of mature virions is facilitated by the sialidase activity of the NA (Fig. 178.2), which clears cell surface sialic acids from the HAs on the nascent virion^{155,450} (see Fig. 178.1).

Nonstructural and accessory proteins are typically not incorporated into the virus.^{212,492,493} (Fig. 178.3). The nonstructural protein NS-1 has multiple functions within the cell, primarily in countering the antiviral response.¹⁶⁷ The influenza A and B virus NS-1 proteins differ in the specific interferon stimulatory genes that they target, and in other cellular binding partners, but perform a similar role in the life cycle.²³⁹ The accessory protein PB1-F2, which is expressed from an alternate start codon in the +1 reading frame of the PB1 gene segment, is variably present in the genome and is variable in length.^{7,65,421} When present as the full-length version, PB1-F2 targets mitochondria inducing cell death and triggering an inflammatory response.^{5,6,79,295} The functions of multiple other accessory proteins are only now being elucidated, but many appear to impact viral and cellular gene regulation (Table 178.1).^{212,462,492,494}

FIG. 178.1 Influenza A virus life cycle in cells. (Modified from McCullers JA. The role of punctuated evolution in the pathogenicity of influenza viruses. In: Scheld WM, Hughes JM, Whitley RJ, eds. *Emerging Infections*. Washington, DC: ASM Press; 2016.)

FIG. 178.2 Electron micrograph of an influenza virion with gold particle labeling of neuraminidase molecules to highlight their polar distribution. The other visible spikes are hemagglutinin glycoproteins. (Modified from Peltola VT, Murti KG, McCullers JA. Influenza virus neuraminidase contributes to secondary bacterial pneumonia. *J Infect Dis*. 2005;192:249-257.)

Classification

Influenza viruses are segmented, negative strand, RNA viruses (see Fig. 178.3). They are divided based on divergence of nucleotide sequences and by functional coding strategies into four types, termed A, B, C, and D. Influenza B viruses diverged evolutionarily from influenza A viruses

between 100 and 350 years ago and are stably adapted to humans.³⁴⁹ Influenza B viruses share a functional organizational strategy with influenza A viruses, having homologous versions of 10 proteins important for the life cycle encoded on 8 RNA gene segments (see Table 178.1). A number of accessory proteins with varying functions differ between the types. Influenza C viruses are thought to have diverged from influenza A viruses much further in antiquity, and have a slightly different organization with seven gene segments encoding nine proteins.⁴⁶⁸ The hemagglutination and sialidase functions of influenza C viruses are combined in a hemagglutinin-esterase-fusion protein; evolutionary remnants of the esterase domain can be found in the influenza A virus HA. Influenza C viruses are very stably adapted to humans and undergo much less evolutionary change over time than the other types. Influenza D viruses have to this point been found only in cattle and swine and are distantly related to influenza C viruses.¹⁷³

Influenza A viruses are zoonoses that are constantly crossing over from animal reservoirs into humans, causing individual infections and occasionally restricted epidemics.¹⁴⁷ Several times a century one of these zoonotic strains will establish endemicity and circulate for, typically, several decades before being replaced by a new incursion. Human influenza A virus lineages do not fully diverge over this evolutionarily short time period and frequently cross back over into animals such as swine.⁴⁶⁴ Although rare interspecies transmission events have been documented with influenza B viruses (e.g., from humans to harbor seals),³⁵⁶ influenza B and C viruses are predominantly restricted to humans as a “dead-end” adaptation. Influenza D viruses have not been detected in humans,⁴²⁰ although few studies have been performed because of the relatively recent discovery of this type. Individual gene segments of the different influenza virus types have diverged enough evolutionarily that they cannot functionally coexist in a reassortant virus without significant alterations to the noncoding sequences at the termini of the individual gene segments.

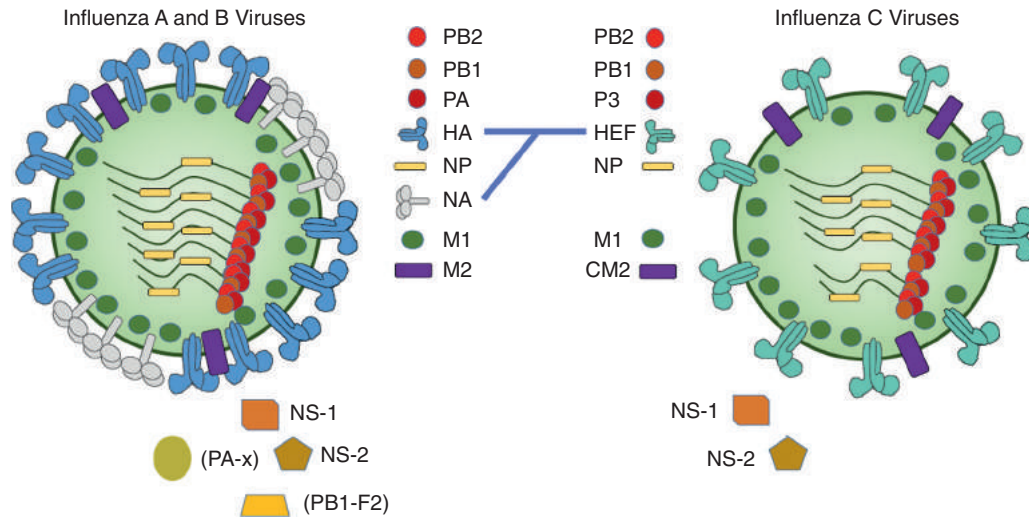

FIG. 178.3 Comparison of influenza A, B, and C virus proteins. Influenza C viruses encode nine known proteins on seven gene segments, two of which are accessory proteins (NS-1 and NS-2). Influenza A and B viruses encode at least 10 proteins on eight gene segments, including many homologous proteins with structures and functions similar to those in influenza C viruses, but also encode a neuraminidase (NA) on an eighth gene segment. In addition, influenza A viruses encode several other accessory proteins including PA-X and PB1-F2 that are not found in influenza B and C viruses (indicated by parentheses), and influenza B viruses encode an accessory protein termed NB on the NA gene segment. The hemagglutinin-esterase-fusion (HEF) protein of influenza C viruses performs similar functions in the life cycle, as do the hemagglutinin (HA) and NA of influenza A and B viruses. Nomenclature for the three types of virus differs somewhat; the third polymerase of influenza C viruses is termed P3, whereas the M2 of influenza B viruses is termed BM2 (see Table 178.1). (Modified from Wang M, Veit M. Hemagglutinin-esterase-fusion [HEF] protein of influenza C virus. *Protein Cell*. 2016;7:28-45.)

TABLE 178.1 Influenza A, B, and C Virus Proteins			
Segment	Type	Gene/Product	Function
1. PB2	A, B, C	Basic polymerase 2	Part of transcription and replication complex
2. PB1	A, B, C	Basic polymerase 1	Part of transcription and replication complex
	A	PB1-F2	Cell death via mitochondrial targeting
	B	PB1-N40	Unknown
3. PA	A, B	Acid polymerase	Part of transcription and replication complex
P3	C	Polymerase	Part of transcription and replication complex
	A	PA-X	Host shutoff endonuclease
	A	PA-N155	Unknown
	A	PA-N182	Unknown
4. HA	A, B	Hemagglutinin	Attachment and fusion
HEF	C	Hemagglutinin-esterase-fusion	Attachment, fusion, and esterase activity
5. NP	A, B, C	Nucleoprotein	Scaffolding for viral ribonucleoproteins
6. NA	A, B	Neuraminidase	Sialidase facilitating budding
		NB	Ion channel?
7. M	A, B, C	Matrix protein 1	Primary structural protein of virions
	A	Matrix protein 2	Ion channel
	B	BM2	Ion channel
	C	CM2	Ion channel
	A	M42	Alternate form of matrix protein 2?
8. NS	A, B, C	Nonstructural gene 1	Multifunctional including interferon inhibition
	A, B, C	Nonstructural gene 2	Nuclear export
	A	Nonstructural gene 3	Unknown

Influenza A viruses are subtyped by serologic characterization of the two surface glycoproteins, HA and NA. Historically, this nomenclature was adopted because HA and NA are the major antigens of the virus. Thus far, 18 HA subtypes and 11 NA subtypes have been identified in nature.⁴⁴⁶ The majority of these subtypes and many of their various possible combinations of HA and NA pairs are found in the wild bird reservoirs of the world.⁵¹³ Only H1, H2, and H3 and N1 and N2 have been demonstrated to form endemic lineages in humans, with the major

caveat that virologic data are only available for the past century. Thus, it is presently unclear whether there are difficult or insurmountable restrictions on other subtypes crossing over into humans and circulating widely, or if this limited sample is a recency bias. However, there have been numerous instances of interspecies transmission from birds or swine with other subtypes that have not, to this point, established endemicity.^{147,218,259,367} A variety of these subtypes can cause epidemics in domestic poultry, such as chickens, ducks, turkey, and quail, whereas

a more restricted set have been found in mammals such as swine, horses, cats, and dogs.^{7,170,313,513} Subtypes containing the H17, H18, N10, and N11 glycoproteins have been exclusively detected in bats to this point.⁴⁴⁶

ECOLOGY

Animal Reservoirs

The primary reservoir for influenza viruses is migratory waterfowl, including ducks and shorebirds of the orders Anseriformes (ducks, geese, swans) and Charadriiformes (shorebirds, gulls, alcids).^{152,480,513} Sixteen of the 18 HA subtypes and nine of the 11 NA subtypes have been found in wild birds. Infections are asymptomatic, and the natural site of replication in birds is the gastrointestinal tract. Virus is shed in the feces into the environment and transmission between wild waterfowl is by the fecal-oral route. Free virus can be isolated from bird droppings on the shore and from the water of lakes where the birds congregate for breeding prior to migration.²³⁷ There are multiple north-south migratory flyways for these birds, some of which span thousands of miles.³⁴⁰ It is likely that young waterfowl are infected by contaminated water in the lakes prior to migration, and then carry the viruses with them, leaving it behind in their feces along the route.²¹

A number of domestic species, primarily poultry such as chickens, turkeys, quail, and domesticated ducks, come into direct contact with infected waterfowl during their migration.^{131,365,512} Viruses may cross over into these populations intact, or may reassort with existing lineages in the domestic poultry to form new viruses. Some of these viruses can cause severe respiratory disease in species such as chicken and turkeys, causing epizootics with high mortality rates. Symptomatic disease will often result in large-scale culling of birds to prevent further spread, with resulting economic losses.^{1,154,418} Inapparent infections also occur, and viruses can be maintained for prolonged periods of time in farms or in live bird markets, where they may come into contact with other species of birds or with mammals such as swine. Avian strains are typically classified as highly pathogenic avian influenza viruses (HPAI) or low pathogenicity avian influenza viruses (LPAI) based on the presence or absence of a multibasic cleavage site in the HA (a cleavage site containing the amino acid motif RX(R/K)R↓G or R(R/K)XR↓G, where X is any amino acid and the downward arrow indicates the site of cleavage).^{38,331} With a typical cleavage site, LPAI are restricted to the respiratory tract, where furin-like proteases are available, and may cause inapparent, mild, or moderate disease.^{38,128,331} The HA of HPAI with a multibasic cleavage site, however, can be cleaved by a wide variety of host proteases, allowing systemic spread and high mortality. Most avian influenza viruses are LPAI; HPAI are currently limited to a subset of H5 and H7 strains.

Infections in domestic ducks are typically gastrointestinal and asymptomatic, as is seen in their wild counterparts.^{237,435} Swine have been considered somewhat unusual for many years, as they are susceptible to both avian influenza viruses and to human strains, raising the possibility of reassortment and generation of novel strains capable of establishing lineages in mammals.^{259,464} Pigs were therefore proposed to be a “mixing vessel” that could act as an intermediate host in the creation of new pandemic strains.³⁹⁶ Indeed, the 2009 H1N1 pandemic appears to have arisen in just such a manner.³⁶⁶ However, other viruses with pandemic potential have arisen through adaptation and reassortment in birds, indicating that this mechanism is not universal.

Reassortment and Establishment of New Lineages

Influenza viruses reassort frequently in nature in humans and in animals.^{268,314,507} There appear to be functional limitations on what specific pairings are possible, but a wide variety of HA and NA combinations are seen.^{222,391} Structurally, HAs can be placed into several related groups and share similarities in function.^{428,429} Individual gene segments can form evolutionary lineages that may or may not match well with other gene products following reassortment, resulting in low-fitness or high-fitness viruses. There also appear to be functional limitations on which gene constellations can be tolerated in which species, since, outside of waterfowl, a restricted set of viruses is typically found in any one species. For example, H3N8 viruses have established endemicity in dogs, while both H3N8 and H7N7 have formed lineages in horses.^{77,426} Cats

can be infected with human H1N1 and H3N2 strains, but also are susceptible to HPAI H5N1 viruses.^{170,241,313,361} Swine may be the most interesting mammalian species, as they are more permissive of multiple subtypes.^{131,204,259,464,465} This is thought to be due to the frequency and distribution of the major forms of sialic acids, which serve as receptors for the influenza virus through binding to HA. Birds including waterfowl typically display terminal sialic acids with an alpha-2,3 galactose linker, and most avian influenza viruses predominantly recognize this moiety.^{180,291} Human viruses predominantly recognize alpha-2,6 sialic acids because of the relative frequency and distribution of the two versions in the human respiratory tract, a difference that creates a species barrier to zoonotic infection directly from wild waterfowl.²⁸⁹ Pigs, however, display both types of sialic acids and can be infected by viruses with either receptor preference, facilitating dual infections and potentially avian-human virus reassortment events.^{277,396,397}

Swine viruses have an evolutionary history that in some ways parallels that of humans. The “classic” H1N1 lineage is believed to have entered swine in 1918 at the same time that it emerged in humans.³²⁸ This lineage remained stable in the United States for many decades, maintained in an endemic cycle in swine and causing only mild disease. Multiple lineages circulated in Europe in the 1970s and 1980s, including a variant of the classic swine strain, H3N2 strains descended from the 1968 pandemic strain, and a novel avian H1N1 strain.⁴⁶⁴ In 1998 the classic H1N1 strain began to evolve in the United States through acquisition of new gene segments via reassortment. The first event led to the emergence of a new strain termed the “double reassortant” H3N2, composed of classic swine genes and human genes from an H3N2 strain. This was quickly replaced by a novel “triple reassortant” that took two new avian genes from the wild bird population.⁴⁷⁷ This variant not only spread widely throughout the world in the ensuing decade, but was a very promiscuous strain, reassorting frequently with circulating human viruses to generate new lineages.⁴⁶⁴

Zoonoses

Many of these novel viruses generated by reassortment between wild birds and domestic species have the potential to infect humans. Incursions of multiple subtypes have occurred in diverse areas of the world, typically through close association of humans with domestic animals. Bird markets, where poultry can be bought live for later consumption, have been shown to be a source of many of these outbreaks in regions where this practice is common, such as Southeast Asia and North Africa.⁴¹⁸ An outbreak with an HPAI H5N1 strain in Hong Kong in 1997 infected 18 persons, resulting in six deaths and was halted only by closing the markets and culling all birds on the island.^{154,365,482} This virus reemerged in 2003 in mainland China¹⁵⁴ and has since spread to poultry across the world, with zoonotic infections of more than 850 humans and a 53% case fatality rate.⁵⁰¹ A similarly concerning HPAI H7N9 strain emerged in 2013 in China and has infected more than 790 persons¹¹⁹ with a 41% case fatality rate. H9N2, H7N7, and H5N6 avian influenza viruses have also caused limited outbreaks in humans.^{126,125,263,262,469} In the United States, zoonotic infections have most frequently come from contact with swine, often affecting children who visited state fairs and came into close contact with pigs.^{147,464,496} More than 350 infections and one death have been detected during outbreaks from swine variant subtypes including H1N2, H1N2, and H3N2 viruses.³³⁷ Asymptomatic infections are probably also common, as poultry workers, workers in swine abattoirs, and others with close contact with species that harbor endemic lineages frequently have serologic evidence of past infection without a clinically apparent illness.^{70,280}

SURVEILLANCE

Animals

Because of the frequency of zoonotic infections and the pandemic potential of many of these strains, surveillance of influenza viruses in animals is essential both to improve our understanding of the ecology and evolution of these pathogens, and to provide an early warning of possible strains of special significance, such as newly emerging HPAI. These strains have the potential to cause huge economic losses through epidemic spread and through the culling of animals that is necessary

to halt disease progression in a population and to reassure the public of the safety of the food supply. Some of these strains are likely to also possess pandemic potential. A set of molecular signatures of virulence in humans is being established that should allow improved pandemic planning through surveillance and genetic analysis of these emerging strains.^{304,305,421}

Surveillance of wild aquatic birds was established by the WHO Collaborating Center for Studies of the Ecology of Influenza Viruses at St. Jude Children's Research Hospital in Memphis in 1976. There are six Collaborating Centers at present, including Centers in Atlanta at the CDC, in London, Tokyo, Beijing, and in Melbourne. However, only the Memphis site concentrates on animal viruses. Samples of feces are collected along the migratory flyways, and the recovered viruses are subtyped and sequenced. Surveillance of swine in the United States was added in the late 1990s, and domestic poultry surveillance began in multiple locations by multiple governmental and scientific groups following the H5N1 outbreaks in the early 2000s. Organizations including the WHO, the World Organization for Animal Health, and the United Nations Food and Agricultural Organization global networks report outbreaks in member states of animal influenza viruses, particularly HPAI H5 and H7 strains.

Humans

Virologic surveillance in humans is coordinated globally by the WHO Collaborating Centers and the WHO Global Influenza Response and Surveillance System,⁵⁰² which was established in 1952. Approximately 143 national centers in 113 member states participate by performing influenza virus testing, isolation, typing, and subtyping. Health care facilities participating in surveillance send samples from patients with influenza-like illness to these national centers for testing; viral isolates are then forwarded to the WHO Collaborating Centers for further investigation, including antigenic characterization, genetic sequencing, and antiviral susceptibility testing. The WHO Collaborating Centers share these data for decisions on annual vaccine composition and pre-pandemic vaccine development. In the United States, approximately 140 state, governmental, and hospital laboratories conduct surveillance, perform testing, and collect viral specimens that are ultimately sent to CDC for more detailed characterization. CDC generates a weekly surveillance report that can be accessed at <http://www.cdc.gov/flu/weekly/>.

Disease

Influenza disease surveillance is also coordinated globally by the WHO, although the degree of surveillance in individual countries varies widely. The WHO Global Influenza Programme publishes standards for estimating disease burden and publishes biweekly summaries of national data from about 100 countries.⁵⁰² Disease surveillance for influenza began in the 19th century as an outgrowth of the desire to better measure causes of mortality in populations. In 1847, the eminent London epidemiologist William Farr, remembered chiefly for his assistance to John Snow in determining that cholera was a waterborne disease, coined the term "excess mortality" to describe the increase in deaths that occurred during the influenza season that were attributed on medical certificates to causes other than influenza itself. Using this concept, he developed in detail the methodology used today to quantitate mortality in influenza epidemics.^{115,252} Selwyn Collins of the US Public Health Service then further refined the terms by which we classify outcomes after influenza in a series of thorough and detailed reports on epidemic mortality in the early part of the 20th century.⁷³⁻⁷⁶ Today, data are collected from 122 cities, covering about one third of the US population, on deaths from pneumonia and influenza (P&I) and reported weekly by CDC. P&I mortality includes deaths from the primary viral infection as well as from secondary bacterial pneumonia and are considered together because they are difficult to distinguish using mortality data. This measure does not include deaths attributed to other causes such as exacerbation of an underlying condition by the viral infection. This provides a proxy for the severity of any given influenza season, by comparing the level of excess mortality to the seasonal baseline. Influenza-associated pediatric mortality surveillance began in 2003 and is now reported separately from excess mortality.

Surveillance for influenza-associated hospitalizations began in the United States in 2003 in children and in 2005 in adults through the Influenza Hospitalization Surveillance Network (FluSurv-NET) at the CDC.⁶⁴ Currently, hospitals in 13 states participate by collecting data on age and clinical characteristics of persons with severe influenza. This allows estimation of age-specific hospitalization rates, description of disease presentation, and determination of comorbid conditions for weekly reporting. Surveillance for influenza-like illness in outpatients is performed at more than 2900 health care providers, which report more than 36 million outpatient visits annually through the Outpatient Influenza-like Illness Surveillance Network (ILINet). This allows estimation of the percentage of clinician visits attributable to influenza-like illness as a proxy for the prevalence of influenza in each state or US territory.

EVOLUTION AND ADAPTATION

Pandemics

Pandemics of influenza occur several times a century when a novel influenza A virus enters humans and spreads worldwide. According to Edwin Kilbourne's framework,^{227,302} a virus must meet three criteria to be considered pandemic: (1) a novel HA protein to which most of the population is immunologically naïve, allowing a high clinical attack rate, (2) ease of transmission enabling worldwide spread, and (3) the ability to cause severe disease. Four pandemics have taken place in the past 100 years. In 1918, an H1N1 subtype virus entered humans from the animal reservoir, causing severe disease and killing more than 40 million people worldwide. This virus adapted to humans and circulated until 1957, when it was replaced by an H2N2 subtype virus that took part of its gene constellation from the circulating H1N1 strain, and the remainder from an avian source (Fig. 178.4). The 1957 pandemic was severe, killing several million persons, but not on the same scale as that of 1918. In 1968 another novel strain emerged, again by reassortment. This H3N2 virus had a novel HA, but retained the NA and several other genes from the 1957 strain. Disease and mortality were milder than in previous pandemics, perhaps because of the retention of the NA antigen from the previously circulating strain. Adapted versions of this virus continue to circulate today. This virus was joined in circulation in humans in 1977 when a 1950 version of the previously circulating H1N1 strain was released from a frozen source. Although this virus achieved worldwide circulation and continues to be endemic in humans today, cocirculating with H3N2 strains, this event was not considered to be a pandemic because much of the population was immune and little disease ensued.

In 2009, the most recent pandemic strain emerged as a complex mixture of genes of avian, human, and swine derivation.³⁶⁶ It was again of the H1N1 subtype, but was most antigenically similar to the 1918 strain among viruses that circulated in the 20th century. Because of this, only older persons who experienced influenza in the 1930s and 1940s and persons who had received the 1976 "swine flu" vaccine had any cross-reactive immunity.^{312,382} Sero-archaeologic evidence suggests that as far back as the mid-1850s, H1, H2, and H3 subtype viruses have successively replaced each other as pandemic strains. It is not known whether this recycling phenomenon is limited to these subtypes because of factors presently not understood, or whether other subtypes are also capable of causing pandemics.^{328,440} The repeated incursions of highly pathogenic avian influenza viruses of the H5N1 subtype into humans since 1997 have created significant concern that a truly novel pandemic strain could arise, but as yet these viruses seem incapable of sustaining chains of transmission in humans.^{154,260}

Adaptation

Common characteristics of RNA viruses such as influenza virus are use of a low-fidelity polymerase coupled with lack of proofreading mechanisms to correct base-pair mismatches.⁴⁰⁶ This results in a high mutation rate and the opportunity for significant variation between influenza viruses to arise under specific conditions. The rapid cycle time and high mutation rate generate a large pool of "quasi-species" variants that interact together, complementing each other by providing flexibility as environmental conditions change.³⁰⁰ As a result of this quasi-species-driven diversity, influenza viruses undergo not only positive selection for traits that aid

FIG. 178.4 Pandemic timeline. Four major lineages of influenza A virus have established endemicity in humans in the past 100 years. The 1957 and 1968 pandemic viruses were reassortants that included genes from the previously circulating viruses that they replaced. The 1918 and 2009 pandemic strains came directly from animal reservoirs. The seasonal H1N1 lineage, which circulated early in the 20th century, was replaced in 1957 but reemerged in 1976 and co-circulated for 32 years with seasonal H3N2 strains. (From McCullers JA. The role of punctuated evolution in the pathogenicity of influenza viruses. In: Scheld WM, Hughes JM, Whitley RJ, eds. *Emerging Infections*. Washington, DC: ASM Press; 2016.)

in adaptation, but also negative (purifying) selection for disadvantageous traits.³⁰⁵ These selection events can be at the level of mutation of individual gene segments, or via reassortment to acquire completely new gene segments that are a better fit for the evolutionary pressure being applied to the quasi-species pool. Because small RNA viruses have limited genome sizes to facilitate rapid replication and easier packaging, they typically have complex coding strategies with multiple gene products capable of being expressed from any individual gene or gene segment.^{194,492-494} Mutations of nonessential gene products may result in expression, deletion, truncation, or other alterations to these accessory proteins changing their function and role in the life cycle.^{5,7,421} Influenza viruses tend to adapt very rapidly (on a scale of years) to positive selection pressure and more slowly (on a scale of decades) to lose or modify undesirable traits through negative selection.^{46,156,495}

Rapid Evolution

Several common scenarios are known to drive evolution of influenza A viruses through positive selection. The most striking is establishing a lineage in a new host through a cross-species jump.^{222,391} In humans this occurs immediately following the introduction of a new pandemic strain. The virus evolves rapidly for several years, then slows, and eventually (after decades) reaches an equilibrium such that, in the absence of other sources of positive selection, most genes are not changing except through gradual negative selection for improved fitness in the host.⁴⁹⁵ The most common positive selection pressure is from antibodies induced either by natural infection or by vaccination. This typically results in mutations in the HA and NA, since they are the primary targets of the immune system. These events, termed antigenic drift, occur seasonally and are a combination of mutations around the receptor binding site of the HA that alter antigenicity and bystander or compensatory structural changes. Antiviral drug use is another commonly encountered selective pressure. Rapid evolution of the NA can be seen in sites related to NA activity following introduction of neuraminidase inhibitor antivirals into a population.⁵⁰⁶ Finally, reassortment is a common event, both within human virus populations and between human and animal strains. The presence of gene products from different influenza A virus lineages in a newly reassorted virus causes functional mismatches that drive selection of genes coding for variants of proteins that work better together. A classic example is the need for a balance of HA binding to sialic acids to enable entry and NA sialidase activity to facilitate budding.^{222,223} Reassortment-induced mismatches are corrected by evolutionary change.⁴⁷²

EPIDEMIOLOGY

Seasonality and Transmission

Seasonal influenza is primarily a disease of children, with clinical attack rates of 20% to 30% during some epidemics. In addition to having the

largest burden of infection, children exhibit a high social contact rate,^{158,278} facilitating transmission.⁴¹⁵ They also possess a relative lack of cross-reactive immunity, allowing unrestricted replication and shedding of large quantities of the virus. However, most deaths are in persons with chronic comorbidities, so mortality is concentrated in older persons. The excess mortality rate for influenza A viruses varies significantly by strain and season, based on both the degree of preexisting immunity in the population, the potency of viral virulence factors, and how well the circulating viruses support secondary bacterial infections from regionally endemic bacterial strains. Because influenza B viruses do not have an animal reservoir and are well adapted to humans, the epidemiology of these viruses resembles that of well-adapted seasonal strains with a high clinical attack rate in children and little mortality outside of those with underlying chronic illnesses. The epidemiology of influenza C viruses is poorly understood at present, but it may cause epidemics related to antigenic drift and emergence of new strains similar to the other influenza virus types.²⁹³

Human-to-human transmission of influenza viruses can occur by contact, large droplet, and aerosol routes.^{8,60,478} Since most viruses are expelled during coughing and sneezing, direct contact with infected secretions or contaminated objects is thought to dominate in most settings. Transmission is affected by both temperature and humidity and is favored in cold conditions and significantly diminished in the setting of high humidity.^{274,275} It has been suggested that aerosol transmission is more efficient in cool, dry environments, facilitating epidemic spread when optimal conditions are met. Most outbreaks in temperate regions therefore occur in the winter months when the aerosol transmission route is favored. However, a low level of infection can be detected year-round when testing is employed. In tropical parts of the world, circulation of viruses can occur in any season, with the timing of peaks of disease being associated with poorly understood climatic changes.⁶⁷

Herd immunity plays some role in the seasonality of influenza. Antigenic drift can lead to larger epidemics, and conversely lack of significant drift can restrict disease mostly to naïve subjects such as children or to those with comorbidities and increased susceptibility. Pandemic strains appear to transmit efficiently in the summer in temperate climes, likely because of elimination of the contribution of herd immunity; the increased availability of susceptible hosts may overcome the temperature and humidity barriers to transmission. For example, the largest peaks of disease during the 2009 H1N1 pandemic occurred in the summer in many parts of the world.^{225,243} The relative ability of influenza viruses to transmit is expressed by a term called the reproductive number R_0 , which represents the average number of persons an infected individual will themselves infect.¹²⁴ Any value over 1.0 suggests that sustained transmission is possible and therefore an outbreak can occur. Seasonal strains of influenza virus have an R_0 in the range of 1.3 to 1.7, which is much lower than comparable viruses such as measles,

which may have an R_0 of 10 to 15. The R_0 of the 2009 pandemic strain varied between 1.1 and 2.0, depending on the population studied.²⁴⁷ Most zoonotic infections, such as with the recent incursions of HPAI H5N1 viruses in Southeast Asia, have an R_0 below 1.0, a factor in these viruses failing to achieve endemicity.²⁴⁰

Global Disease Burden

Until recently, comprehensive surveillance had been conducted predominantly in high-income, developed countries. Data from recent decades suggested that the rate of hospitalization was highest in children younger than 1 year and adults older than 65 years. The great majority of deaths are in persons older than 65 years. Hospitalization rates by age for children have been estimated in the United States at approximately 130 to 150 per 100,000 for age less than 1 year, 36 to 39 per 100,000 for ages 1 to 4 years, and 11 per 100,000 for ages 5 to 17 years.^{144,515} However, these are likely underestimates by a factor of about 2, because only a proportion of patients are tested for influenza, many testing methods have poor sensitivity and specificity, and hospitalizations for influenza are often coded as something else.^{144,381,413,515} Adjusting for this systematic bias, it was estimated that during three influenza seasons from 2010 to 2013, the total number of hospitalizations in US children (<18 years) varied from approximately 10,000 to 42,000, the number of ICU admissions from 1900 to 7600, and the number of deaths from 50 to 840 annually.³⁸¹ Because only about 0.5% of children with symptomatic influenza are hospitalized,⁴¹³ it can be further extrapolated that about 2.2 to 9.3 million illnesses occur in children annually in the United States. The severity of any particular influenza season varies considerably based on the predominant type or subtype circulating, the overall burden of disease, and the hospitalization rate of children in different age groups.⁵⁷

Globally, few systematically collected data have been available until very recently. A recent meta-analysis of studies using polymerase chain reaction (PCR) diagnostic testing suggests that the rate of hospitalization is about threefold higher in developing compared to industrialized countries²⁵⁰ and is highest in Africa and Southeast Asia.^{132,191,250,316,416} On average, an estimated 900,000 children are hospitalized for influenza annually, with 96.3% of these hospital stays occurring in the developing world. In a different meta-analysis, it was recently estimated that in 2008 more than 90 million influenza-associated illnesses occurred in children younger than 5 years, with more than 20 million cases of influenza-associated acute lower respiratory tract infections (ALRI) and 1 million cases of severe ALRI.³³⁴ In this study, 93% to 97% of all ALRI and severe ALRI were in the developing world. These numbers are probably also underestimates, as in many developing parts of the world passive surveillance fails to detect many persons who for cultural preferences or because of financial constraints do not seek health care,³⁷⁹ or use alternative forms of health care such as private clinics where surveillance is not taking place.²⁶⁶ Prospective community- or household-based surveillance may better capture the true incidence of disease.^{81,149,341,353}

Coinfections

The epidemiology of influenza-associated coinfections remains difficult to assess with any accuracy because it is difficult to attribute disease or death to influenza instead of its complications,^{73,473} and because most of the burden of disease occurs in outpatient settings, where few studies have comprehensively assessed coinfections.³⁰⁴ It is also difficult to assign an etiology for clinical syndromes such as otitis media and pneumonia; it is particularly difficult to define precisely the contribution to the pathogenesis of disease of the various pathogens that can be co-detected in infected individuals when sensitive methodologies are used.²¹⁴ Current testing paradigms for identifying bacterial pathogens within the lung suffer from a lack of both sensitivity and specificity.³⁴⁸ Recent advances in use of PCR-based assays for detection of viral pathogens help in identifying viral causes of pneumonia,²¹³ but positive tests from the upper respiratory tract do not always correlate with the etiology of deep lung infections. Direct examination of the middle ear is possible through otoscopy and tympanocentesis, such that etiology is better established for otitis media, where viruses are the predominant pathogens in the conjugate vaccine era and coinfections are common.³⁴⁷ An issue

specific to coinfections is that sequential infections may be more difficult to accurately diagnose if the preceding pathogen (e.g., influenza) has resolved by the time the patient presents for medical attention due to secondary bacterial pneumonia.⁴⁸⁴ Because viruses other than influenza are also found in coinfections, specific attribution of etiology is difficult in this “hit and run” scenario. Despite these challenges, there is an increasing appreciation that most episodes of otitis media and community-acquired pneumonia, particularly when associated with influenza, result from coinfections.³⁰³

The 1918 pandemic was comprehensively studied by leading microbiologists and pathologists of the era, and many of these early studies have been reanalyzed in recent years.^{43,68} Estimates from clinical and autopsy series suggest that more than 95% of all severe illnesses and deaths were complicated by bacterial pathogens.³²⁹ Many of the victims of this pandemic were children and healthy young adults.⁴⁴ This contrasts sharply with seasonal influenza, in which mortality is most often seen in persons with chronic medical conditions, a propensity that shifts the age distribution toward an older population. Respiratory pathogens such as *Streptococcus pneumoniae*, *Staphylococcus aureus*, *Haemophilus influenzae*, and *Streptococcus pyogenes* (group A streptococcus) were all identified as common pathogens in various studies.⁴⁴ The overall picture that is evident from these data is that severe disease and mortality were linked to the presence of secondary invaders, with factors such as variations in which strains were endemic, modified by personal immunity, dictating the epidemiology in a particular region.^{44,219,303}

Beginning in the antibiotic age,²¹⁶ the overall pattern of mortality in the subsequent 1957 and 1968 pandemics was closer in character to seasonal influenza than that seen in the pandemic of 1918. Pneumonia accounted for a higher proportion of deaths in 1957–58 and 1968–69^{33,45,399,405,449} than during most of the preceding interpandemic years,^{76,89} but did not approach the 95% seen in 1918.³²⁹ Similar to seasonal influenza, the highest incidence of disease was in healthy children and young adults of school and working age, with an attack rate that averaged about 40%.⁴⁴¹ In contrast to 1918, however, most excess deaths were linked to cardiopulmonary conditions and thus occurred primarily in older persons.^{89,187,449} When pneumonia was associated with mortality in 1957–58, *S. aureus* was the most frequent secondary invader.^{185,186,287,355,387} The clinical course was often fulminant, with death occurring in less than 7 days, and severe pulmonary edema and hemorrhage were commonly found on autopsy.¹⁸⁷ The higher incidence of *S. aureus* was a striking departure from previous pandemics and seasonal epidemics and was initially blamed on the use of antibiotics that were effective against *S. pneumoniae*, *S. pyogenes*, and many strains of *H. influenzae*, but not against the emerging antibiotic-resistant strains of *S. aureus* prevalent in hospitals at the time.^{216,387} However, in 1968–69, the clinical attack rate and incidence of pneumonia were comparable to rates in 1957, but *S. pneumoniae* was once again the predominant pathogen. *S. aureus* was diagnosed more frequently during the 1968 pandemic than in the immediately preceding interpandemic years,³⁹⁹ but was not the dominant etiologic agent as it had been in 1957–58 despite similar availability of antibiotics.

Although *S. pneumoniae* was considered the most common cause of secondary pneumonia in the decades after the 1968 pandemic, in the past two decades *S. aureus* has emerged as a cause of fulminant pneumonia in association with influenza in many parts of the world, particularly in children.^{117,142} The USA300 and USA400 clonotypes of *S. aureus* seem to be particularly likely to cause secondary pneumonia with influenza compared to other circulating strains, for unclear reasons. *H. influenzae* has become less prominent as a cause of secondary bacterial pneumonia with the introduction of the type B conjugate vaccine, although it remains important in regions of the world with poor vaccine coverage.⁴⁷⁶ Group A streptococcus is entirely absent from many series describing community-acquired pneumonia in association with viruses and is typically third in incidence when it does appear.⁶³

During the 2009 H1N1 pandemic,⁹³ in a departure from the previous two pandemics, mortality rates were similar to recent seasonal epidemics. However, most deaths occurred in older children and young adults, often with no underlying chronic conditions, and morbidity rates were high.^{92,113} Respiratory deaths associated with an aberrant response to the virus accounted for most of this mortality in previously healthy

persons.^{92,325,382} It remains unclear what the precise impact of secondary bacterial disease was; some estimates put excess mortality from influenza and pneumonia as low as 10%,⁶² a rate lower than many seasonal epidemics.⁴¹⁷ In careful studies of severely ill or fatal cases, bacterial pneumonia was found to complicate around one third of infections.^{51,103,113,141,294,408} *S. pneumoniae* and *S. aureus* were the most common etiologies of secondary bacterial pneumonia, with regional variation in which was more prominent.^{51,141,294,342,385} It is unclear whether the prominence of *S. aureus* in 2009–10 was due to the strain-specific features of the recently emerged USA300 clonotype, or was a reflection of increased penetrance of pneumococcal vaccination in the last decade.³³⁶ *S. pyogenes* was absent as a secondary pathogen from many series, but was surprisingly frequent in others, suggesting further differences in regional endemicity of the most common co-pathogens.^{9,51} In some carefully conducted studies, few serious bacterial superinfections were identified despite extensive sampling to detect them.²⁴³ When present, however, it was clear that bacterial superinfections from *S. pneumoniae* or *S. aureus* resulted in worse outcomes.^{99,342,359,385}

Economic Impact

Influenza has a tremendous economic impact from direct costs (outpatient visits, testing, medications, travel costs, hospital stays), intervention costs (vaccines, school closures), and indirect costs (missed days of work for parents or guardians). This impact varies based on the severity of the season, cultural and infrastructure factors that vary by country, and the characteristics of the patient population. Estimates of economic impact for a mild pandemic in the developed world range from \$81 million in a mid-sized North American city¹⁰ to \$330 million in Hong Kong, a city of 7 million persons.⁴⁹⁷ In this latter study, outpatient costs for children with influenza ranged from \$236 for an illness not requiring medical attention, to \$542 for an illness requiring an outpatient visit, to \$1926 for a hospitalization, and cost \$352,284 for each death.^{319,497} Using 2003 data, the overall impact of seasonal influenza in the United States has been estimated at \$87.1 billion per year, based on 31.4 million outpatient visits, 3.1 million hospitalization days, and 610,660 life-years lost.³²⁴ Economic impact is lower in low-to-middle-income countries, primarily because the direct costs are lower for treatment and hospitalization,⁹⁵ and patients may not choose to seek health care as often for cultural reasons.³⁷⁹ However, indirect costs reflected in productivity losses are higher in low-to-middle-income countries, and these are the countries least able to sustain such an impact.⁹⁵ In children, the economic impact is highest in young children under 5 years, especially under 2 years, and in those with chronic medical conditions.³¹⁹ Interestingly, public health interventions such as school closings, although effective at reducing the burden of disease, are estimated to increase costs due to loss of productivity,⁴⁹⁷ whereas use of antivirals and vaccines can both reduce the burden and reduce costs.¹⁰

High-Risk Pediatric Groups

Age and chronic medical conditions are the predominant risk factors for increased severity of influenza. Hospitalization rates for influenza by age presents as a U-shaped curve, with rates in children highest in infants younger than 1 year, but still higher in the 1- to 2-year range and 2- to 5-year range than in school-age children.^{211,338,350,443} Children with chronic medical conditions have a higher rate of outpatient and emergency department use and higher rate of hospitalization in all groups compared to children without such conditions. Children with chronic respiratory diseases, such as cystic fibrosis, are at risk for hospitalization and worse outcomes from influenza.^{8,378,474} Because asthma is such a common chronic disease of children, affecting about 8% of children in the United States,⁵⁹ co-occurrence of asthma in children hospitalized for influenza is common and asthma has long also been considered a risk factor for hospitalization.^{8,55} However, recent retrospective studies have found that asthmatics were less likely to have complications from influenza, including pneumonia and intensive care admission, and were less likely to die compared to nonasthmatics.^{94,139,273,315,459} It has been proposed that the immune profile of the lungs in asthmatics, in contrast to the situation in cystic fibrosis,³⁷⁸ may diminish replication of influenza viruses and ameliorate disease.³⁹⁵ Other common chronic conditions of children associated with increased rates of hospitalization include cardiovascular (except hypertension alone), renal, hepatic,

hematologic (including sickle cell disease), neurologic or neurodevelopmental (including cerebral palsy, epilepsy, stroke, and intellectual disability), and metabolic (including diabetes mellitus) disorders.⁸ Children with cancer or other forms of immunosuppression are at a particularly²⁵⁶ high risk for complications and poor outcomes from influenza, including prolonged shedding, pneumonia, delay in chemotherapy, and death.^{129,165}

Mortality in Children

Despite high rates of morbidity, influenza-associated mortality is uncommon in children in the developed world. Since pediatric influenza-associated deaths became a nationally notifiable occurrence in the United States in 2004,³⁶⁴ an annual average of 93 deaths (range, 37 to 171) have been attributed to seasonal influenza in children.⁵⁷ Surprisingly, up to 43% of these influenza-associated fatalities were in healthy children without comorbidities.⁴⁹⁸ Of those with one or more comorbidities, neurologic and developmental disorders (33%) were most common, followed by respiratory disorders (26%), chromosomal or genetic disorders (12%), and congenital heart or other cardiac disease (11%). In the group of children without preexisting chronic medical problems, 55% had bacterial pneumonia as a complication, and 46% died before being admitted to a hospital.⁴⁹⁸ *S. aureus* was the most common bacterial pathogen complicating influenza in these cases, accounting for about half of diagnoses.^{117,498} It is likely that these are underestimates of the actual number of deaths, because mandatory reporting does not capture all patients for a variety of reasons, including lack of testing and categorization of deaths as attributable to other processes, such as complications of comorbidities. Outside the United States, the case fatality rate is thought to be much higher, with the total burden worldwide attributable to influenza estimated in one study as between 28,000 and 111,500 deaths in children under 5 years.³³⁴

Avian Influenza

Humans who have close contact with avian species such as chickens, ducks, quail, geese, or turkeys are frequently exposed to avian influenza viruses.^{198,335} However, because of barriers to cross-species transmission, symptomatic infections are rare. Infections resulting in respiratory illness have been identified for multiple subtypes, both LPAI and HPAI strains.^{125,246,260,365,501} Many of the reported LPAI H9N2 infections have occurred in children.^{47,367} Person-to-person transmission of LPAI has not been reported.⁴⁵⁷ LPAI virus infections commonly cause uncomplicated illness with fever, myalgias, and upper respiratory tract symptoms such as cough, sore throat, rhinorrhea, and nasal congestion.^{47,457} Both LPAI and HPAI can cause conjunctivitis, either with or without accompanying respiratory tract disease.^{121,343,377} H7 subtype viruses seem to have particular tropism for the eye.^{121,343,377,451}

The first case of HPAI H5N1 infection was reported in a child in Hong Kong in 1997.⁷² Eighteen cases, including 11 children, were identified in Hong Kong in 1997 prior to the closing of all live bird markets and slaughter of all poultry on the island.⁵¹⁴ The spectrum of disease in children ranged from uncomplicated influenza-like illness to acute respiratory distress syndrome (ARDS), multiorgan failure, and death. This virus reemerged in 2003 in mainland China and, since that time, has continued to circulate throughout Southeast Asia and parts of the Middle East and Africa in wild birds, with outbreaks in domestic poultry and occasional transmission to humans.^{154,217,335,458} Limited chains of human-to-human transmission have been identified, but in most cases direct contact with poultry has been implicated.^{1,26,365,402} However, studies on transmission in ferrets suggest that relatively few mutations are needed to achieve respiratory droplet transmission,^{184,205,392} which could presage improved spread and trigger a pandemic. As of spring 2016, 850 human cases had been confirmed in 15 countries, with 449 deaths (52.8% case fatality ratio).⁵⁰¹ Clinical disease from HPAI H5N1 is often severe or fatal in adults, but can present as a mild upper respiratory tract infection in children.^{41,354} The case fatality ratio is lowest in children, perhaps because they present to medical attention and are hospitalized earlier in the course of illness than with adults.³⁵⁴ Atypical presentations such as gastroenteritis or encephalitis have been seen,¹⁷ and cases have been misdiagnosed as other common febrile diseases such as dengue and typhoid.¹

Other HPAI outbreaks have ranged from conjunctivitis with or without mild respiratory tract illness (H7N3 and H7N7 strains)^{377,451} to more severe disease including ARDS and death (H7N7, H7N9).^{121,126} The current H7N9 outbreak began in 2013 in China, and cases have occurred in Malaysia and Taiwan. To date 778 cases have been identified,¹¹⁹ although very few have been children. Severe disease including ARDS is common, occurring in more than 70% of patients.^{126,263} Diagnosis of avian influenza virus infections including HPAI viruses is made by testing respiratory specimens by reverse transcription (RT)-PCR, targeting persons with a history of travel to an endemic area and contact with poultry. Clinical management is by early initiation of antiviral treatment with an NA inhibitor, and supportive therapy for complications such as respiratory failure, shock, and multiorgan system failure.^{456,487} Nosocomial infection with H5N1 has been reported, and adherence to infection control measures including standard, droplet, and contact precautions with eye protection and enhanced respiratory protection with N95 or equivalent respirators is important to prevent acquisition by health care workers.⁴⁵⁶

Swine Influenza

Swine influenza was first described in association with the 1918 pandemic⁴⁸⁰ and was first isolated in 1930 by Richard E. Shope.⁴¹¹ Experimentally infected swine could be demonstrated to have respiratory disease when coinfecting with *H. influenzae suis*. Most human strains of influenza and some avian strains can infect pigs, and human viruses often cross the species barrier, reassort in pigs, and establish lineages. Swine influenza can cause viral pneumonia in pigs, typically in the setting of bacterial coinfection.³⁰¹ Sporadic zoonotic infections occur from direct contact with swine, often in children.¹⁴⁸ An outbreak at Fort Dix in 1976 caused great national concern in the United States over the possibility of a new H1N1 pandemic when 13 soldiers were infected and one died.¹³⁰ This fear became reality in 2009 when a reassortant H1N1 strain emerged in swine and started the first pandemic since 1968.⁹³ Fortunately, this virus did not cause high mortality, likely because it was missing several virulence factors associated with virulence and support for secondary bacterial infections.¹⁶² However, multiple other strains currently circulating in swine do possess these virulence factors and do support secondary bacterial infections well, creating the worry that a new, more pathogenic pandemic strain will emerge from this reservoir.⁴⁸³ In recent years, multiple cases of swine influenza acquisition have been documented at state fairs and other agricultural exhibitions where direct contact with pigs is common.⁵⁶

CLINICAL MANIFESTATIONS

Primary Influenza

Influenza has a short, 2- to 3-day incubation period, after which both respiratory and systemic symptoms appear together. After the first several days of illness when systemic symptoms dominate the clinical course, a transition takes place and systemic symptoms subside and cough and other respiratory tract-related symptoms become more prominent. Systemic symptoms include fever, chills, malaise, headache, dizziness, gastrointestinal disturbances, and myalgias.^{83,253,258} An erythematous maculopapular rash may be present briefly but is not a common or prominent sign of infection. Common respiratory symptoms include cough, sore throat, rhinitis, nasal congestion, and eye irritation. Cough may be productive or nonproductive and may persist for weeks or longer. Disease in adolescents and older children is similar to that of adults and is dominated by the triad of fever, cough, and myalgias (Table 178.2). Cough is less prominent in younger children and is sometimes absent entirely in infants. Myalgias are much less frequent in children than in adults. Gastrointestinal symptoms are frequent in young children and can manifest as vomiting, diarrhea, or abdominal pain. Infants may have fever and diarrhea as their sole presenting signs. Gastrointestinal symptomatology was more common during the 2009 H1N1 pandemic than is typically observed in seasonal influenza, and commonly affected older children and adults.^{352,413} Apnea and a sepsis-like syndrome can also occur in neonates and infants. In 5% to 30% of cases, infection is asymptomatic; this rate varies somewhat by strain.^{207,363}

TABLE 178.2 Clinical Manifestations of Influenza

Symptoms	Infants	Children	Adults
Fever	++	+++	+++

Modified from McCullers JA. Influenza. In: Elzouki AY, Harfi HA, Nazer H, et al, eds. *Textbook of Clinical Pediatrics*. 2nd ed. New York: Springer; 2012.

Most children with influenza have a normal white blood cell count, but both leukopenia and leukocytosis can be seen. Leukocytosis with a predominance of neutrophils can be a sign of secondary bacterial infection, but can also occur with uncomplicated influenza. Blood chemistries are typically normal unless dehydration or complications are present. Influenza A and influenza B are indistinguishable clinically, although specific strains may have a predilection for certain clinical syndromes, and influenza B is more likely to cause clinical disease in younger children than in adults.³⁷¹ Influenza C viruses are more likely to be asymptomatic or pauci-symptomatic, but when symptomatic disease is present it can be severe, resulting in hospitalization and complications.²⁹²

Complications

Both viral and bacterial complications are common during childhood influenza. Otitis media, sinusitis, and pneumonia all can be due either to the primary viral infection or to manifestations of coinfecting bacteria.^{160,183,243,303,369} Laryngotracheobronchitis (croup) can be a manifestation of acute influenza in young children. Viral pneumonia was more common with the 2009 pandemic H1N1 strain than in recent seasons with other influenza A or B virus strains and was particularly prevalent in older children and young adults.^{91-93,113} This appears to be due both to unique characteristics of this virus and to an aberrant immune response causing immunopathology in the lung. Lack of surface glycosylation on the HA coupled with a polymorphism at amino acid 222 of the HA allows deeper penetration into the lung and diminished clearance by surfactant protein D.^{141,193,384,463,510} Enhanced inflammation triggered by aberrant antibody and T-cell memory responses and innate recognition of the poorly glycosylated HA during transit through the Golgi contribute to acute lung injury.^{197,325,471} Bacterial pneumonia was relatively uncommon during the 2009 pandemic compared to previous pandemics, but when superinfections were present, outcomes were worse and hospitalization was prolonged.^{90,342,344,359,385,459} Otitis media associated with influenza may present as a mild, serous exudate if it is solely due to the virus, but in young children, mixed viral-bacterial infections are common and a painful, purulent exudate may result. Symptoms of sinusitis are common during acute influenza, and opacification of the sinuses can be seen on computed tomography in a significant proportion of affected persons. Bacterial sinusitis may result as a secondary complication, manifest as increased pain and a return of fever after an initial period of recovery.¹⁶⁰

Mild elevations of hepatic transaminases occur commonly during acute influenza. Severe elevations, accompanied by steatosis, may be

seen in Reye syndrome in the setting of salicylate exposure.^{27,168,434} Reye syndrome appears to be more common with influenza B virus, and encephalopathy, hepatic failure, and death may result. The incidence of this complication has decreased markedly since warnings to avoid aspirin in febrile children were issued, but occasional cases still occur.^{27,168,346} An acute myositis manifest by severe pain and tenderness of both calves may occur during the early convalescence stage. This syndrome may have a rapid onset and is accompanied by elevations of serum creatine kinase and aspartate transaminase and, occasionally, rhabdomyolysis in severe cases.⁴⁷⁵ Cardiac complications including myocarditis and pericarditis are associated rarely with influenza.^{210,452} The pathogenesis of these complications is unclear, as virus is rarely identified in affected tissues.

Severe neurologic symptoms can be associated with influenza.⁴⁰⁴ These complications are confined almost exclusively to young children who are naïve to the virus and have never received the influenza vaccine.^{143,330} Mild neurologic complications, such as exacerbation of a seizure disorder, occur more frequently in patients with preexisting neurologic disorders.³⁷⁶ Febrile seizures are relatively common and uncomplicated in young children with or without a previous diagnosis of seizure disorder, and up to 30% of all febrile seizures of childhood are due to influenza.^{110,489} Encephalopathy during influenza can present with a variety of symptoms and signs, but mental status changes ranging from delirium to behavioral disturbances to coma are most prominent.^{307,339} Cranial nerve pareses are unusual, as are meningitic presentations. Cerebrospinal fluid (CSF) examination is typically normal or reveals a mild pleocytosis, and virus can be detected in CSF by PCR or in biopsy or autopsy material from affected brains in about 15% of cases. Diagnosis is made on a clinical basis, with supporting information from electroencephalography (EEG) and magnetic resonance imaging (MRI) to rule out other causes. Computed tomography (CT) scans and MRI either are normal or demonstrate diffuse edema and are generally unhelpful in establishing a definitive diagnosis or prognosis.²⁰⁹ EEG typically shows a general slowing without an acute focus. A subset of patients present with a more fulminant course and have findings on CT or MRI suggestive of necrosis in the subthalamic regions, a syndrome termed acute necrotizing encephalopathy.^{203,209} Influenza-associated encephalopathy is uncommon in much of the world during circulation of seasonal strains, but was relatively common in Japan in the late 1990s and early 2000s for reasons that remain unclear. During the 2009 H1N1 pandemic, neurologic complications were more common than in preceding years, and older children were affected more commonly than is typically seen with seasonal influenza.³⁷⁶

PATHOLOGY

The hallmark of pandemic influenza is pneumonitis with diffuse alveolar damage, since these viruses typically penetrate well into the lower respiratory tract.^{141,186,242,294,329,408,439} Hemorrhage, fibrin deposition, edema, and formation of hyaline membranes are common in the alveolar spaces. Submucosal congestion, hemorrhage, inflammation, and necrosis are common in the trachea and bronchi. In severe cases typical features of ARDS are seen. Myocarditis can be seen on autopsy in fatal cases.^{242,358} Findings suggestive of bacterial pneumonia, primarily manifest as a neutrophilic infiltrate with consolidation, may be superimposed on this pathologic picture.^{51,68,141,141,329,439} Antigen testing for bacteria in autopsy cases has been useful in recent studies to define the differences between primary viral and secondary bacterial pneumonia.⁵¹ Seasonal influenza rarely presents as severe, primary viral lower respiratory tract disease; a mild to moderate tracheobronchitis is a more common presentation. Infiltration of lymphocytes in a peribronchial and perivascular distribution is typical.^{140,242,439} The epithelial lining of the major airways is predominantly affected, with cell death and sloughing of epithelial cells exposing basement membrane elements, upon which extracellular matrix material is deposited. Ciliated cells may also be killed during infection, or may merely be functionally disrupted so that beat frequency and coordination of beat direction are altered, reducing clearance of mucus secretions.³⁶² Pathologic alterations in other affected organs (e.g., heart, brain), are most commonly nonspecific, with edema and inflammatory changes present.^{358,432}

PATHOGENESIS

Virulence Factors

Hemagglutinin

The surface glycoprotein HA contributes to virulence both by facilitating efficient infection and by triggering inflammatory immune responses. HAs that have recently emerged from the avian reservoirs (including many pandemic strains) demonstrate enhanced virulence by both of these mechanisms. Avian origin HAs will typically have residual specificity for α -2,3-sialic acids, the predominant form in birds, while gaining specificity for α -2,6-sialic acids,^{111,508} which are the predominant receptor for influenza A viruses in the human respiratory tract. It has been suggested that this residual α -2,3 recognition facilitates lower respiratory tract invasion by H5N1 viruses due to the deep lung distribution of α -2,3-sialic acids in humans.^{71,460} Recently, a role for glycosylation in modulation of innate immune surveillance has been recognized. Influenza virus glycoproteins are flagged in the ER as “nonself” when they are poorly glycosylated, triggering the unfolded protein response and ER stress.¹⁹⁷ Mediated by IRE1 α , signal transduction downstream of the c-Jun N-terminal kinase (JNK) drives inflammatory responses in the respiratory tract leading to acute lung injury. This contributes substantially to the pathology during influenza virus infections, particularly pandemic strains.

Neuraminidase

The role of NA in virulence is as a complement to HA, facilitating budding by cleaving sialic acids and disrupting sialic acid–HA binding. This requires maintenance of a balance between HA binding affinity and NA activity; viruses with NA activity that is too high relative to HA affinity have difficulty binding and establishing an infection, whereas viruses with too little relative NA activity have difficulty budding. The NA also contributes substantially to support for bacterial coinfections.³⁶⁹ Sialic acid cleavage uncovers receptors for bacteria³⁰⁶ and releases sialic acids into the extracellular medium where they can be used as a carbon source, facilitating bacterial growth.⁴¹⁴ The strength of the cleavage activity of the NA correlates broadly with the severity of epidemic influenza; circulating viruses with high NA activity map to some of the most severe seasons of the last century, and pandemic strains tend to have high NA activity.³⁶⁹

Polymerase Genes and PB1-F2

Much like the HA, the polymerase complex of genes (PB1, PA, PB2) are essential to infection, and viruses with high-efficiency polymerases replicate faster and can cause more pathology by outpacing the immune responses. This contributes to the high virulence of recent HPAI H5N1 and H7N9 strains.^{436,509} The PA and PB1 proteins from certain virulent viruses also contribute to pathogenesis by interfering with RIG-I-mediated recognition of viral RNPs during the first stages of replication, which blocks early interferon signaling preventing cellular control of the infection.^{264,265} PB1-F2 is a small, multifunctional accessory protein of influenza A viruses that is evolutionarily conserved in avian strains, including the pandemic strains from 1918, 1957, and 1968.⁴²¹ It contributes to pathogenicity by triggering cell death through mitochondrial interactions and through support of secondary bacterial infections.^{295,296}

Nonstructural Protein 1

NS-1 is another nonstructural protein with several functions.¹⁶⁷ Its main role is as an antagonist of interferon and the antiviral response; artificial viruses without canonical NS-1 activity are severely attenuated.¹²⁷ The influenza A virus NS-1 also contains three potential src homology binding domains, one SH2bm and two SH3bm, which are conserved in many avian lineages. Most avian strains excluding H5N1 and H9N2 variants share a consensus sequence from amino acids 212 to 217 defining an SH3(II)bm.¹⁹⁵ This domain allows binding of NS-1 to c-Abl and subsequent inhibition of its functions in lung homeostasis. The end result of this blockade is acute lung injury and greatly increased pathogenicity of viruses that carry the motif.¹⁹⁶

Evolution of Virulence

Because influenza A viruses are all zoonoses from the wild bird reservoirs of the world, newly emergent pandemic strains of avian origin must

adapt to their new hosts. Many of the virulence factors just described are found in pandemic strains or other HPAI capable of infecting humans, but are lost during subsequent evolution.^{304,305} The binding affinity of HA for α -2,3-sialic acids tends to weaken or disappear over time during adaptation. Over several decades, the HAs of strains that achieve endemicity in humans gain additional glycans on the head region of the protein, abrogating innate sensing in the ER and diminishing the resulting inflammatory response in the lung.^{197,463} Considerably less lung pathology then occurs during the infection with seasonal strains.¹⁹⁷ These heavily glycosylated viruses are also more easily neutralized by collagenous lectins such as surfactant protein D and are cleared from the lower respiratory tract more efficiently.^{380,463}

Reassortant strains with mismatched HA/NA pairs, such as the 1968 pandemic virus, undergo rapid adaptation, with the NA often evolving to match HA and regain the balance between HA affinity and NA cleavage.⁴⁷² Changes in NA activity either to match HA affinity changes during adaptation or in response to neuraminidase inhibitors¹⁵⁶ have a downstream impact on pathogenicity through change in support for secondary bacterial infections. Loss of NA activity as a compensatory mechanism to escape these drugs in a population with frequent treatment¹⁵⁷ should diminish pathogenicity in this manner.

Because its role in the life cycle of the virus is dispensable in mammalian hosts, nonfunctional forms of PB1-F2 are negatively selected over decades during adaptation in both humans and swine. These pathogenic functions are lost through truncation to shorter forms that lack the active sites in the C-terminal portion of the protein (typically to 11 or 56 amino acids, reduced from the full length of 87 to 90 amino acids⁴²¹), or through loss of the start codon itself or mutation of the active site amino acids to a neutral or even antibacterial configuration.⁵ Strains lacking the cytotoxic functions supported by the C-terminal domain do not support secondary bacterial infections very efficiently, and in the human H3N2 lineage, the antibacterial effect appears to be a form of viral-bacterial warfare supporting the virus in its host niche.^{5,297} The 1918 pandemic strain expressed an avian NS-1 that contained the SH3(II)bm domain that inhibits c-Abl; however, the motif was mutated during adaptation of the H1N1 lineage to humans to a form that could not bind c-Abl and did not enhance acute lung injury.¹⁹⁶ The overall pattern for changes in virulence is a gradual decrease in pathogenicity of viruses during adaptation to the mammalian host after emerging from birds.³⁰⁵ Evolutionarily, this is likely to benefit the virus by helping it avoid immune surveillance, facilitating transmission and a continuation of the adapted lineage.

Animal Models

The earliest examples of modeling influenza infections in animals came during the 1918 pandemic prior to the discovery of viruses. Wherry and Butterfield passed unfiltered sputum from ill patients by aerosol into a variety of animal species, including guinea pigs, mice, and rats.⁴⁸⁶ Approximately a third of the exposed animals developed pneumonia and died, likely from a combination of the virus and coinfecting bacteria. Although a number of attempts had been made to prove influenza was caused by a filterable agent both before and after the 1918 pandemic, it was not until the 1926 demonstration, by Dunkin and Laidlaw using dogs and ferrets, that canine distemper was caused by a virus¹⁰⁶⁻¹⁰⁸ that similar experiments in pigs were successfully conducted for influenza virus by Richard Shope.⁴¹¹ Pigs remain a viable model for study of both human and swine viruses,⁵¹⁶ although size and husbandry requirements limit their use to specialized facilities.

The first well-controlled study of secondary bacterial pneumonia in mice using an influenza virus was conducted by Thomas Francis and Mercedes V. de Torregosa in 1945.¹²³ They reported that *H. influenzae*, *S. pneumoniae*, and *S. aureus* could all cause a fatal pneumonia in an intranasal coinfection model with the mouse-adapted influenza virus A/Puerto Rico/8/34 (PR8). Today, most laboratory models of viral-bacterial coinfection are derived from a similar sequential infection model that uses influenza virus PR8 followed by a laboratory strain of *S. pneumoniae*, which faithfully recapitulates many of the hallmarks of the clinical syndrome of severe secondary bacterial pneumonia.³⁰⁹ Because mouse models are limited to a select set of mouse-adapted viruses, however, ferrets are commonly used as a second animal model to study

human viruses. Early studies of influenza infectivity, transmission, and isolation of viruses were done in ferrets¹¹ in the 1930s and 1940s, and ferrets remain the favorite model for study of respiratory droplet transmission.^{184,205} Mice, ferrets, and chinchillas have all been used in vaccine studies,^{200,202,389} and chinchillas are particularly useful in studies of influenza-associated otitis media because of the ease of access to their middle ear space by tympanocentesis.^{137,368} Guinea pigs are also used as an alternative model for transmission.^{275,427}

Research and Modeling

Unraveling the relationships between pathogen replication and the resulting airway alterations and inflammatory responses that are driving host pathology and disease is complicated. Animal models have limitations in terms of both what can be studied and the ethics of using animals when alternatives are available. Kinetic mathematical models are a robust means of analyzing experimental results and explaining biologic phenomena without testing every scenario experimentally. A growing body of work modeling in vivo influenza virus infections has led to improved knowledge about the viral life cycle, viral control by the host, pathogenic differences in strains, and efficacy of antiviral treatment (reviewed in references 24, 422, and 424). These models have characterized the spread of virus during early infection and yielded estimates of strain-specific viral infection and production rates, infected cell life spans, and infectious virus half-life, all of which are not amenable to experimental investigation. It is likely that this field will continue to advance rapidly in the coming years and will be useful both to aid experimental interpretation of findings in animal models, and in some cases to replace animal studies altogether.

Dual Use Research

A significant controversy arose when two papers were published in 2012^{184,205} that demonstrated that HPAI H5N1 viruses could be adapted to transmit between ferrets by the airborne route with only a few amino acid changes using reverse genetics systems.¹⁹⁰ This was a critically important discovery, as it not only serves as a warning that such viruses could evolve in nature, perhaps relatively easily,³⁹² but also allows targeted surveillance in H5N1 strains for these amino acid changes as a part of pandemic planning. Two concerns arose following the announcement of this discovery: the possibility that accidental release of these pathogens might cause a pandemic, and the fear that terrorists would either acquire such a virus or create it themselves for intentional release.²⁷⁰ This led to unprecedented steps by the Dutch government to censor one of the publications by making it subject to “export laws,”¹¹² and by the US government to halt all research and research funding on “gain of function” studies for influenza viruses. It has been argued by prominent scientists who study influenza that, while the risks related to failures of biocontainment and biosecurity are real, albeit minuscule, the true threat is nature.⁴⁷⁹ Influenza viruses evolve and adapt easily and in unpredictable ways, and if such a virus is possible (as shown by the published studies), nature is likely to produce it. Deliberately eschewing research and open scientific discourse that might prevent another pandemic on the scale of 1918, which killed more than 50 million persons worldwide, is near-sighted and dangerous to the public health.⁴⁷⁹ Four years after publication of the original papers, the National Science Advisory Board on Biosecurity in the United States continues to debate the appropriate regulatory framework for balancing the ethical concerns about dual-use research with the scientific gains that are needed to prevent the next pandemic, and research remains in a hiatus.³⁵¹

DIAGNOSIS

Differential Diagnosis

Because influenza can manifest as a variety of clinical syndromes, the differential diagnosis is broad. This is particularly true in infants, who may not have common signs of infection such as cough. Depending on the particular disease manifestations, many other pathogens can be either the primary cause or a co-pathogen. Other respiratory viruses such as parainfluenzaviruses, respiratory syncytial virus, human metapneumovirus, rhinoviruses, and coronaviruses should be considered in the differential diagnosis for upper respiratory tract infections, otitis

media, and croup, particularly if they are circulating in the community in the same time frame. Accuracy of clinical diagnoses of specific respiratory viruses is very poor, with a sensitivity for diagnosing influenza as low as 38% and a positive predictive value of only 32%.³⁷⁰ Influenza A and B viruses cannot be distinguished clinically by signs and symptoms of the presentation.⁸⁷ In general, testing for influenza is valuable to understand when influenza is circulating in a community, but testing is not necessary to establish the diagnosis in every patient once an epidemic is underway.

Bacterial causes of epiglottitis such as *H. influenzae*, *S. aureus*, and *S. pneumoniae* must also be considered in the child with croup, particularly if acutely ill. *S. pneumoniae*, *S. aureus*, and *S. pyogenes* are common lower respiratory tract co-pathogens with influenza, but must also be considered in the differential diagnosis as primary agents of disease along with other common causes of community-acquired pneumonia such as *Mycoplasma pneumoniae* and *Chlamydia pneumoniae*. Numerous viral and bacterial pathogens can also present with fever and diarrhea, although gastrointestinal symptomatology with influenza is generally mild and the diarrhea nonbloody. The encephalopathy syndrome associated with influenza can mimic either bacterial meningitis or a viral encephalitis, so multiple causes must be considered. Finally, neonates with influenza can present with lethargy, poor circulation, and apnea without other typical signs of influenza, so other causes of sepsis must be considered.

Diagnostic Testing

Classically, influenza has been diagnosed on the basis of a compatible clinical presentation in the setting of supportive epidemiology, with testing being used to establish circulation. Local or regional data suggesting increased presentation to primary care centers coupled with an increased rate of laboratory diagnosis of influenza can usually be relied on to indicate the start of wintertime epidemics in temperate climes. Sentinel programs to track influenza are in place in many countries (e.g., through the CDC in the United States⁶⁴) and internationally through the WHO. As an important epidemiologic clue, influenza will more frequently affect both adults and children together than other causes of similar clinical syndromes. In this context, an age-appropriate clinical presentation can usually be assumed to be influenza and appropriate measures taken without specific diagnostic testing. Testing is generally most useful to inform treatment decisions. A positive test may be useful to prompt antiviral treatment and avoid unnecessary use of antibiotics, whereas a negative test may reduce the cost of treatment by avoiding antiviral treatment. In the hospital setting, testing may also help to guide the need for or type of isolation and personal protective equipment to be employed. Chest radiographs may be helpful in some cases to confirm lower respiratory tract involvement or define a complicating bacterial pneumonia, which may need antibacterial therapy.

Three methods of diagnosis of influenza are in widespread use at present. Point-of-care testing in outpatient settings is typically limited to antigen-based testing. This is accomplished through the use of inexpensive kits that use colorimetric changes upon antibody recognition of virus in nasal swab material to rapidly demonstrate the presence of antigen.²⁴⁴ Some tests can distinguish type A from type B influenza, but none can currently subtype influenza A strains or distinguish specific strains within an influenza A subtype or between the two major influenza B lineages. These kits typically have a low sensitivity but reasonable specificity compared to PCR, so although a positive result is useful for directing care, a negative result does not rule out influenza.³²² Use in the proper setting when influenza is likely to be circulating is important, as the pretest probability of influenza being present can have a dramatic impact on positive predictive value with tests with poor sensitivity.¹⁵⁰ Rapid antigen testing is also commonly employed in hospitals as a point-of-care diagnostic in acute care settings such as emergency rooms, but typically with a more sensitive and specific test as a backup, performed in a central laboratory.² Two methods are commonly employed in tertiary care settings. A fluorescent antibody test where clinical material from a nasal swab or nasal wash is used as the sample, and the presence of virus is determined by microscopy to detect fluorescence of dyes bound to those antibodies which recognize the virus, has been in common use for decades. This method is more sensitive and specific than rapid

antigen tests, but may take several hours to achieve a result and requires special training and experience. This has been replaced in many centers by the use of PCR-based testing, particularly using rapid and sensitive real-time PCR assays. These assays have the advantages of quick turnaround times, improved sensitivity and specificity compared to all other methods, and can be designed to differentiate viruses by type, subtype, and even strain.^{25,244} In parallel, similar methods are now available to rapidly sequence portions of the viral genome to provide indicators of the most common resistance mutations.^{98,438} Other potential methods to diagnose influenza, such as virus isolation or acute and convalescent serology, are now confined to research settings.

MANAGEMENT

Antiviral Therapy

Several antiviral compounds have been developed against influenza virus to interfere with specific events in the replication cycle.²⁹⁹ Among these, two classes of drugs are currently approved as antiviral agents by the Food and Drug Administration (FDA) of the United States. The adamantanes (amantadine, rimantadine) are inhibitors of viral uncoating, while the NA inhibitors (zanamivir, oseltamivir) interfere with the viral budding process.

Adamantanes

The adamantanes have been shown to be efficacious in the treatment of influenza A virus infection caused by different subtypes (H1N1, H2N2, and H3N2) but are ineffective against influenza B viruses.^{104,177,461,491} Defervescence, improvement in symptoms, resolution of symptoms, and return to normal activity all occurred about 1 day earlier in treated subjects than in those receiving placebo. Although no studies of sufficient size have been performed to convincingly address whether adamantane treatment prevents complications of influenza, animal data²⁹⁸ and a challenge trial in adult volunteers¹⁰⁴ suggest that there is a lack of effect. Efficacy in populations other than healthy adults or when administration is delayed beyond 48 hours has not been studied thoroughly. Prophylaxis of healthy adults during influenza outbreaks showed 71% to 91% efficacy compared to placebo in preventing laboratory-confirmed influenza virus infection in two trials using amantadine,^{102,326} and 85% efficacy using rimantadine in a single trial.¹⁰² A meta-analysis of published clinical data concluded that the major effects of amantadine and rimantadine treatment were to shorten the duration of fever by about 1 day in treated, infected individuals, and prevent about 60% to 70% of influenza cases when used as prophylaxis.²¹⁵

Adamantanes possess two concentration-dependent mechanisms of antiviral action.³⁷⁴ At micromolar concentrations (0.1–5 μ M), adamantanes selectively inhibit two different steps in the replication cycle in a strain-specific manner.¹⁸ Prior to membrane fusion, the low pH of the endosome activates the M2 channel to conduct protons across the viral envelope, which results in the acidification of the viral interior. Adamantanes block the ion channel activity of the M2 protein of influenza A virus, and viral replication is inhibited by the blockade of hydrogen ion flow into the virus particle, principally at the stage of virus entry and uncoating.⁴⁶⁷ Amantadine also acts at a late stage of replication by preventing virus release of certain influenza strains that possess intracellularly cleavable hemagglutinin (HA), in particular the H5 and H7 subtypes. This effect is proposed to result from irreversible conversion of the HA to its low-pH conformation form within the trans-Golgi network in the absence of M2 function.^{32,146}

Rapid development of fully pathogenic and transmissible resistant variants after amantadine or rimantadine treatment and their ineffectiveness against influenza B virus infection are the main drawbacks of M2 blockers.¹⁷⁵ The markers of resistance to adamantanes are well established and include substitution of one of five amino acids (positions 26, 27, 30, 31, and 34) within the transmembrane domain of M2 protein; each change confers resistance to both amantadine and rimantadine.^{31,174,374} Amantadine-resistant influenza A viruses are found among 30% to 80% of isolates after only a few days of drug therapy in both immunocompetent and immunocompromised patients.⁴¹⁰

The incidence of naturally occurring amantadine-resistant variants has increased dramatically since 2003, and these resistant influenza A

(H1N1) and A (H3N2) viruses have spread widely and reached nearly 100% even in countries without substantial amantadine use.^{40,50} For this reason, the US CDC discourages use of M2 inhibitors⁵⁰ except in specific instances with susceptible strains as a part of combination therapy.⁵⁰⁵

Neuraminidase Inhibitors

Development of the NA inhibitors was a significant milestone in antiviral development, as this was the first example of synthesis of such a drug based on the crystal structure of a target enzyme.^{20,230,466} The NA inhibitors zanamivir and oseltamivir were approved by FDA for the treatment and prevention of influenza in 1999. Oseltamivir is not thought to distribute into the brain,⁴³¹ although central nervous system toxicity in juvenile rats with an immature blood-brain barrier led to cautionary warnings about the use of this agent in children under 1 year of age.²³¹ A subsequent study demonstrated that the incidence of neurologic side effects in infants was no greater with oseltamivir than with amantadine,²³¹ suggesting an acceptable safety profile. Reports of neuropsychiatric events in patients taking oseltamivir, particularly in Japan where use is heavy, have prompted many countries to add cautionary warnings to the drug's label. However, it is unclear whether these effects are due to the drug or to influenza itself, which has well-known neurologic side effects.³⁷⁶ In general, adverse events after oral administration of oseltamivir are considered to be mild and include nausea and vomiting. Inhalation of zanamivir is generally well tolerated but may cause bronchospasm in some patients with underlying lung disease.¹⁵⁵

Both oseltamivir and zanamivir are effective and well tolerated in adults treated for natural influenza infection, including hospitalized patients.^{178,345,448} Reduced effectiveness for influenza B viruses as compared to influenza A viruses has been reported for oseltamivir.²²⁴ The therapeutic benefits of NA inhibitors have been reported to include reductions of about 1 day in the time to alleviation of illness, resumption of usual activities, and duration of fever, as well as decreases in illness severity, ancillary medication use, viral titers, and the frequency of antibiotic prescriptions for lower respiratory complications.^{178,345,448} Oseltamivir both decreases the incidence of secondary bacterial pneumonia and reduces the severity of complications in an animal model.²⁹⁸ Similar data are not available from a single, well-powered trial in humans, although a meta-analysis of data from multiple trials suggests that these results can be extrapolated at least to healthy adults.²²⁰ In children, however, oseltamivir was shown to reduce the occurrence of otitis media by 44% compared to placebo.⁴⁸⁸ Retrospective reviews of insurance claims databases suggest that NA inhibitors reduce the risk of otitis media, pneumonia, respiratory illnesses other than pneumonia, and hospitalization in both adults and children.^{159,373}

Both zanamivir and oseltamivir have demonstrated the ability to interrupt household transmission.^{176,485} A meta-analysis of 78 trials during the 2009 pandemic showed a reduced risk of mortality; earlier treatment was associated with a further reduction in risk.³³² Early administration of oseltamivir increases the benefit seen in healthy adults relative to treatment at 48 hours,¹⁶ but no randomized, controlled trials have been conducted studying treatment outside of the first 48 hours, so no data are available to examine the effects of late treatment on prevention of complications. Because persons with chronic illness, who might be more likely to benefit from late treatment as viral control might be established later in such individuals, have typically been excluded from antiviral studies, this question is currently unanswered. Intravenous zanamivir has been used under an emergency investigational new drug program in several hundred hospitalized children and adults with severe illness for whom oral or inhaled therapy was impractical, but efficacy and safety information will require prospective study.⁶¹ Higher doses and longer durations of therapy with oseltamivir (150 mg twice daily for 10 days) have been attempted anecdotally for severe infections with H5N1 subtype viruses or in immunocompromised subjects,^{26,254,321} but no data from randomized trials are available to assess the effectiveness of these measures.

The NA inhibitors were designed based on the knowledge of the three-dimensional structure of the NA complex with sialic acid⁴⁶⁶ and act as competitive inhibitors by binding within the enzyme's active site. The primary function of the NA enzyme in the life cycle of influenza

viruses is to remove sialic acid residues from the surface of the infected cell and from mucins in the respiratory tract, facilitating the release of newly synthesized virus particles and allowing the virus to spread.²⁹⁰ Blockade of this activity prevents virion budding and leads to aggregation of viruses on the cell surface and within the mucosal layer, preventing subsequent infection of new cells.¹⁴⁵

Two mechanisms of resistance to NA inhibitors have been described. The first is mutations within the NA enzyme catalytic site that disrupt a direct interaction with the drug. The second is mutations in the HA that reduce affinity for its receptor, thus compensating for the effect of the drug on NA activity.¹⁵⁵ The most frequently observed mutations for NA inhibitor-resistant variants for influenza A viruses of N1 NA subtype are H275Y and N295S (N1 numbering); for influenza A viruses of N2 NA subtype are R292K and E119V (N2 numbering), and for influenza B viruses are R152K and D198N. Prior to the 2007-08 influenza season, oseltamivir-resistant variants were found in only a small proportion of patients (approximately 4%-8% of children and <1% of adults) after treatment with the NA inhibitor.⁴³⁰ However, rigorous detection techniques identified resistant mutants in 9 of 50 (18%) Japanese children during treatment with oseltamivir.²³⁴ A high level of oseltamivir resistance among influenza H1N1 viruses was reported in many European countries starting in the 2007-08 influenza season.^{100,248}

During the 2009 H1N1 influenza pandemic, almost all tested viruses remained susceptible to oseltamivir and zanamivir. Oseltamivir-resistant variants with H275Y NA mutation were isolated from individuals receiving prophylaxis²³ and from immunocompromised patients⁵² under drug selection pressure. Oseltamivir-resistant variants also have been isolated from untreated patients^{257,517} and from a few community clusters.²⁵⁵ The reasons for the relative paucity of resistant strains and the lack of widespread transmission are not yet clear. However, experimental evidence suggests that the oseltamivir-resistant H275Y mutant of the pandemic 2009 H1N1 virus retained efficient transmission through direct contact in a ferret model, but respiratory droplet transmission was decreased as compared to an oseltamivir-sensitive virus.¹⁰⁵ This suggests that transmission efficiency of the mutants may be decreased, limiting spread between humans.

Steroids

Corticosteroids have been widely used to treat many inflammatory and immune diseases including severe pulmonary infections such as ARDS.³¹⁷ Clinical use of corticosteroids as an adjunctive therapy for treating pneumonia or to reduce cytokine loads during ARDS has been controversial.^{323,401} Most data on their use derives from studies in adults, and data are lacking in children. Despite controversy, the use of steroids in severe influenza, particularly in the setting of ARDS, is common in both adults and children. In a recent prospective case registry analysis in Japan, 33% of children mechanically ventilated for pandemic H1N1 influenza received corticosteroids as part of their therapy.⁴⁴⁵ A similar study in France showed that 40% of children with ARDS from influenza received corticosteroids.⁴² Some randomized controlled clinical trials suggest beneficial activity in treating pneumonia with a significant reduction in the length of hospital stay^{80,318} or a decrease in mortality of patients with septic shock.¹⁴ Based on these studies in severe pneumonia, some have advocated for use in influenza as well.¹³ However, other studies of pneumonia have shown no benefit or harmful outcomes from corticosteroids.^{286,425} Similar findings, including increased secondary bacterial infections and mortality, have also been demonstrated in clinical trials in influenza, although most studies are in adults.^{42,101,229} Animal data suggest that the primary detrimental effect of steroids during influenza treatment is prolongation of viral replication due to suppression of T-cell responses.¹³⁴ Based on these data and expert opinion, the WHO discouraged corticosteroid treatment during the 2009 influenza pandemic.⁵⁰⁰ Generally, consensus expert opinion suggests that the data are insufficient to recommend use of corticosteroids in children for treatment of influenza or ARDS.⁴³⁷ However, children receiving corticosteroids for chronic pulmonary, rheumatologic, or other disorders should not have these drugs withheld.

INFECTION CONTROL

Clinical management of influenza in both the outpatient and inpatient settings requires an infection control plan for prevention of nosocomial

influenza in health care workers and transmission of influenza virus to other patients. All health care workers should receive influenza vaccination.¹⁵³ Influenza vaccine coverage among health care personnel in the United States has increased dramatically from the early 2000s (rates typically ranged from 34–49%¹⁷²) to the mid-2010s (rates of 75–77%).³⁴ Coverage is highest in hospitals, likely because of required reporting instituted in 2013 by the Centers for Medicare & Medicaid Services.²⁶⁷ Educational programs have only a modest impact on vaccination rates.^{311,388} Requiring vaccination as a condition of employment (with few exceptions allowed) improves rates markedly, and hospitals mandating vaccination achieve rates as high as 96%.^{34,267,279} Instituting a policy that requires unvaccinated health care personnel to wear a mask throughout the influenza season when working in patient care areas increases the acceptance rate and may close some of the gaps that persist despite mandates from employers.¹⁰⁹ Unfortunately, vaccination rates among health care workers remain low in many countries other than the United States.^{19,135,388}

Patients with confirmed or suspected influenza should be isolated in single patient rooms, or cohorted with other patients with confirmed infection if this is not possible. Because influenza can transmit by both droplet and aerosol routes, standard, contact, and droplet precautions are recommended, including a gown, gloves, and surgical mask as personal protective equipment (PPE).⁶⁰ Hand hygiene should be employed after removal of PPE. Both soap and water and alcohol-based gels are effective at neutralizing influenza viruses. Enhanced respiratory protection (e.g., fit-tested N95 respirator and goggles or a face shield) should be used during aerosol-generating procedures and when providing care to patients with confirmed or suspected HPAI influenza viruses such as H5N1 or H7N9 strains.^{60,478} Negative-pressure rooms, when available, should be used for isolation of confirmed or suspected cases of HPAI influenza. Antiviral treatment of ill patients and postexposure prophylaxis with an NA inhibitor is effective at reducing infection after exposure of unvaccinated health care personnel and other household contacts.¹⁷¹ In particular, pregnant health care workers should be vaccinated and included in postexposure prophylaxis programs, because the mother and the fetus are at high risk for adverse events from influenza, including primary viral pneumonia and fetal loss.⁴⁴⁴

VACCINES

History

About a decade after the first isolation of influenza viruses, a monovalent, inactivated, whole virus influenza A vaccine was developed by the US military.³⁰⁸ It entered widespread use in the Armed Forces in 1943 and was licensed commercially shortly thereafter in 1945 as a bivalent product with the addition of influenza B antigen. A trivalent vaccine with two type A H1N1 antigens was introduced in 1947.²³⁵ During the 1960s, inactivated, split antigen and subunit vaccines were introduced in an attempt to reduce reactogenicity of whole-virus preparations, a particular concern in children due to side effects such as intense local reactions, fever, and febrile seizures.¹⁹⁹ The development of the master donor virus backbones for the live, attenuated influenza vaccines (LAIV) that were first licensed for human use in 2003 was also accomplished in this decade.²⁸¹ Trivalent influenza vaccines (TIV) containing a type B antigen, and both H1N1 and H3N2 type A antigens have been in use since 1978 following the reemergence of H1N1 strains in 1977. The divergence of influenza B into two antigenically distinct lineages in the 1980s created a problem with vaccine matching, as there was reduced immunogenicity when the “wrong” strain was chosen for inclusion in the vaccine and the circulating strains did not match.³¹⁰ Quadrivalent influenza vaccines (QIV) containing two influenza A antigens and two influenza B antigens were approved in the United States in both LAIV and inactivated forms in 2012 to address this problem through inclusion of both circulating influenza B virus strains.²⁵¹

Strain Selection

A strain selection committee, organized by the WHO, meets twice a year in February (for the Northern Hemisphere) and September (for the Southern Hemisphere). The Committee reviews data on the characteristics of strains circulating in different parts of the world as collected

by the WHO Collaborating Centers.⁴⁹⁹ Characteristics include type and subtype, associated disease and epidemiology data (e.g., severity by outcomes), antigenicity compared to prior vaccine strains as determined by hemagglutination-inhibition assays using ferret sera, and genetic analyses to understand evolution of virulence factors and other markers in strains over time. Taking all of these factors into account, the panel of experts appointed to the committee chooses vaccine strains for the upcoming influenza season, prioritizing those that are likely to be in wide circulation, grow well in eggs to facilitate large-scale production, have the possibility of antigenic drift with reduced population immunity, and are predicted to cause more severe disease. The WHO Collaborating Centers then develop vaccine seed strains through reverse genetics techniques, creating viruses that should grow well in eggs or tissue culture by virtue of internal genes adapted to the planned growth medium, but which have the desired antigenicity due to use of the chosen HA and NA glycoproteins. Individual countries then make a decision on whether to use these seed strains or closely matched alternative strains during production and distribution. In the United States, this decision is made by the FDA's Vaccines and Related Biological Products Advisory Committee shortly after the WHO's February strain selection meeting for the upcoming fall and winter season. In about 7 of 10 years the vaccine is well matched to the circulating strains the following season; in other years significant drift occurs in the intervening months or a minor variant unexpectedly emerges, leading to reduced vaccine efficacy. The process of producing vaccine takes 5 to 8 months for egg-grown viruses and may be limited by the growth properties of individual viruses and production capacity. A 5- to 10-fold reduction in replication capacity of one of the viruses leads to a need for 5 to 10 times as many eggs, with associated increased costs and increased lag time until vaccine is available.⁴⁵³ Many countries outside of the developed world do not have the capacity to produce vaccines and rely on either purchase at reduced cost from manufacturers in developed countries or on vaccine donation programs.²⁴⁵

Immunogenicity

Currently, influenza immunization focuses on induction of immunity to the exposed globular head of the HA glycoprotein.¹¹⁸ For the purpose of vaccine licensure, the serum hemagglutination-inhibition (HI) titer is considered the gold standard correlate of anti-influenza immunity by both the US FDA and the European Agency for the Evaluation of Medicinal Products.^{78,455} This assay indirectly measures the ability of antibodies from sera to disrupt binding of HA to sialic acids on red blood cells, which serves as a correlate for the ability of these antibodies to prevent attachment of the virus to sialic acids on respiratory tract epithelial cells. The initial association between a specific HI titer and protection from clinical illness was made by Thomas Francis Jr,²²⁸ who cited unpublished data when he suggested that an HI titer of 1:32 or better was protective in early clinical trials in the military and in mental institutions.^{320,393} This spurred the use of HI titer as a threshold for protection for licensure purposes, and currently a serum HI titer of 1:40 or greater is defined as a protective response by the FDA and the European Agency for the Evaluation of Medicinal Products.^{78,455} Human vaccination-challenge studies later showed that protection from infection could be conferred in many subjects by a titer between 1:30 and 1:40, but protection was not absolute even over 1:40.^{189,375}

Additional assays that can detect specific immune responses (e.g., microneutralization, enzyme-linked immunosorbent assays [ELISA]) are being tested in laboratory settings and in clinical trials of influenza vaccines and offer additional information about the degree of responsiveness to a vaccine and functional quality of the response.³⁰⁸ However, these assays are not yet useful as stand-alone correlates of protection. Because the mucosa is the site of replication of influenza viruses, there is interest in the development of mucosal correlates of immunity to guide improved vaccine design. IgA antibodies can be detected in the nasal wash of humans after influenza, and they are induced by LAIV vaccines.²⁹ A contribution of IgA antibodies to protective immunity to pulmonary infections can be demonstrated in murine models, but IgA is not required for protection in mice.³⁶⁰ The contribution of IgA to protection in humans is unclear because of the difficulty in obtaining appropriate mucosal samples in humans, compared to the ease with

which secretions from the entire lung surface can be assayed in mice. This lack of appropriate correlates of mucosal immunity makes immunogenicity assessments of mucosal vaccines, such as the licensed LAIV product, difficult. LAIV shows better relative efficacy in some patient populations compared to TIV,²⁸ but generally is accompanied by a modest serum antibody response as measured by HI, so better correlates of immunity are needed. In addition to antibodies toward the HA protein, antibodies to alternative antigens on influenza (e.g., NA, M2) can also be measured and are used in clinical trials to understand the contribution of other forms of immunity to protection, but there are not enough data available in humans to demonstrate utility as correlates of protection.

Pediatric Vaccination

Universal vaccination of all children is recommended in the United States.¹⁵³ In children, influenza vaccines are typically poorly immunogenic in the first several years of life, and prior infection or repeated vaccination is required to boost responses to the vaccine above thresholds predicted to be effective. Current recommendations are for children 6 months to 8 years to be given two doses of vaccine during their first season of vaccination to optimize responses.¹⁵³ Two doses are also required if a child received only one dose in prior seasons, but children with two prior lifetime doses need only one dose each year. Some children with chronic diseases have reduced responses to influenza vaccines, particularly those with immunosuppressive states such as human immunodeficiency virus (HIV) infection or after cancer chemotherapy.^{48,163,164,166} In other chronic conditions, such as sickle cell, responses are not blunted.¹⁶³ Children with cancer or HIV may benefit from two doses of vaccine regardless of past history of vaccine uptake.^{163,164,236} Because no influenza vaccines are licensed for children under 6 months of age, household contacts should be vaccinated to prevent transmission to the infant, and pregnant women should be vaccinated.³⁷² Inactivated influenza vaccine is safe and effective in pregnant women.^{208,442} Because 10% to 20% of all pregnancies end in spontaneous abortion and influenza is one of the causes of early termination of pregnancies, vaccination is protective against spontaneous abortion by preventing an infection that may trigger fetal demise.³⁹ Influenza vaccine is also safe in breastfeeding mothers and provides protection for infants through the breast milk.²⁸³

In the United States, several formulations of inactivated vaccine are available from several different manufacturers, and many have different age ranges for use. In the 2015–16 season, different vaccine products were licensed for use in children, with the lower bound for age set for various preparations at greater than 6 months, 3 years, 4 years, 9 years, or for use only in adults greater than 18 years.¹⁵³ These differing age ranges do not stem from different anticipated safety or efficacy profiles of the vaccines, but from the need to conduct a small clinical trial of immunogenicity in the specific age groups prior to release of each vaccine, leading each company to make a decision on target ages based on cost and timing of their specific trial versus anticipated use and profit margin. A larger age range means a larger, more expensive trial and perhaps a longer time to market. Both trivalent (H1, H3, and B) and quadrivalent (H1, H3, and two strains of B) preparations were available in 2015–16. Preparations were available in multiuse vials, containing trace amounts of thimerosal as a preservative, and as single-dose syringes or vials with or without thimerosal. LAIV was available as a quadrivalent preparation and is indicated for children older than 2 years, excluding immunocompromised patients and children younger than 4 years with asthma or wheezing. Multiple additional preparations are available for adults, including vaccine delivered by needleless intradermal microinjection systems, cell-culture–based vaccines that do not trigger allergic reactions to eggs, and a recombinant protein vaccine.¹⁵³

Influenza vaccines are considered to be safe and well tolerated in children. Common side effects of inactivated vaccines include fever as well as mild and transient pain, tenderness, and/or swelling at the injection site, each generally noted in 10% to 20% of vaccinees.^{161,169,261} Other side effects are extremely rare, and in some cases are linked to specific batches of vaccine. Whole-virus vaccines were associated with higher rates of fever and a clear association with febrile seizures in

children, prompting replacement by split-virus and subunit vaccines in the 1970s.^{199,261,308} Although febrile seizures are still reported with influenza vaccines, and at a somewhat higher incidence during first exposure to the 2009 pandemic vaccine, they are not more common than is seen in the unvaccinated population unless the influenza vaccine is coadministered with pneumococcal conjugate vaccine.^{22,161,169,261} More severe skin reactions resembling cellulitis occur at a rate of about 1 in 10,000 and typically resolve in 2 or 3 days without antibiotics.¹⁶⁹ Other rare side effects linked to specific vaccine products include anaphylaxis (one per million exposures); Guillain-Barré syndrome (one per 100,000 exposures), predominantly during the 1976 “swine flu” vaccine program⁴⁰³; narcolepsy (one to six per 100,000 exposures), limited to a set of European countries using an adjuvanted H1N1 pandemic vaccine in 2009^{3,4}; and Bell palsy (odds ratio of 84, 1–2 months after receipt of vaccine, compared to controls), limited to persons receiving a specific vaccine in Switzerland in the 2000–01 season.³³³ Subsequent population-based studies from large databases suggest that none of these rare side effects are clearly linked to inactivated influenza vaccines in general, but either can be attributed to specific products through unclear mechanisms or are spurious associations because they do not occur at a rate above that of the unvaccinated population.^{161,169,261,390} Because Guillain-Barré syndrome and Bell palsy can be caused by influenza itself, the vaccine is considered protective against these conditions outside of the epidemics cited. LAIV is also safe and well tolerated. About half of children receiving LAIV report nasal congestion; other side effects including fever, sore throat, and headache are mild and transient and occur in less than 5% of recipients.^{28,30,35,233}

EFFICACY AND EFFECTIVENESS

Vaccine efficacy is defined as the ability of a vaccine to prevent laboratory-diagnosed infection in the context of a clinical trial.¹¹⁶ By contrast, effectiveness is a broader term indicating the ability of a vaccine to provide a benefit to the vaccinee; this benefit may be by preventing various manifestations of disease, ameliorating symptoms, abrogating subsequent transmission, facilitating a return to normal activities sooner, or providing cost savings for a person, business, or society. Both inactivated influenza vaccines and LAIV are efficacious when compared to placebo.^{28,30,84,232,233} Generally, inactivated influenza vaccine and LAIV have similar efficacy when compared head-to-head in children of all ages as a group, although LAIV is typically superior in young children when immunity to the live virus contained in the vaccine is lowest and immunogenicity of inactivated vaccines is poorest.²⁸ Although it has not been well studied in older adults, it is likely that decreased replication of the vaccine virus in individuals with significant lifetime exposure to influenza may lead to decreased efficacy of LAIV in this population. There are strong data suggesting that inactivated vaccines are not as immunogenic or efficacious in older people as they are in healthy younger adults, which has led to the development of high-dose inactivated vaccines for this age group.^{54,114} Several generalizations can be made on vaccine efficacy from data accumulated over the past several decades. First, there are age gradients of efficacy for each vaccine type. LAIV is most efficacious in very young children, with decreasing efficacy seen with increasing age and immune experience. Inactivated influenza vaccines are most efficacious in healthy older children and young adults and have much less efficacy in young children, particularly under 2 years of age, and in older persons. Second, there is great variability in efficacy based on underlying comorbidities in an individual and season, subtype, and vaccine strain such that efficacy of the vaccine in particular patient groups and from year to year is very difficult to predict.

Influenza vaccines provide a variety of benefits beyond direct prevention of infection in the individual vaccinated. Influenza vaccines are generally effective at preventing most medically attended illnesses due to influenza, as well as severe influenza requiring hospitalization.^{36,69,82,221,470} Estimates generally range from 60% to 70% for prevention of influenza-like illness for well-matched strains. Despite concerns about immunogenicity, effectiveness against hospitalization in children with chronic medical conditions is typically very good, around 70%.³⁷ Both inactivated influenza vaccines and LAIV are effective at reducing the incidence of

acute otitis media and otitis media with effusion.^{86,181,182,357} Effectiveness against influenza-related pneumonia is between 50% and 60%.^{151,284} Both LAIV and inactivated vaccines are cost saving or cost effective in children and show a higher cost benefit in children who are at increased risk for complications of influenza.^{188,276,285,394,409,423} The value of cost savings varies considerably by severity of the influenza season and match of the vaccine to the circulating strains, but is typically estimated between \$5 and \$150 per child immunized. However, these are probably low estimates for vaccine programs in children, as most analyses do not consider the impact of herd immunity and decreased transmission from children into other groups, including older persons and other vulnerable populations.^{120,136,138,383,433}

PANDEMIC PREPAREDNESS

Careful planning and several critical advances are needed in order for the world to be prepared for the inevitable next influenza pandemic (Table 178.3). At the most basic level, the magnitude and nature of the threat must be understood and monitored with thorough and structured surveillance. Currently, continuous surveillance in birds takes place at a limited number of sites relative to the scope of wild bird ecology and is often confined to specific countries or regions with artificial borders.^{21,152,513} Targeted surveillance takes place during outbreaks,^{66,262} and more than 80 countries have some sort of surveillance program,²⁸² but these are poorly coordinated and do not share standards or reporting measures. There are even fewer structured, continuous programs for monitoring swine influenza,^{204,259,464} so it is unsurprising that the emergence of the 2009 pandemic strain went undetected until multiple human cases had occurred and transmission of the virus could not be constrained.⁵³ Programs should be aimed at understanding the patterns of circulation of influenza viruses in their natural hosts, aquatic waterfowl, and incidental hosts at the human-avian interface such as domestic poultry and swine.^{269,481} In addition to surveillance, further research is required.^{303,305} Answers to many basic questions are needed, such as, “Why are HPAI strains so lethal? What will allow transmission to humans from birds, or between humans? Can H5N1, H7N9, or other pandemic precursors reassort with currently circulating human strains? What patient groups or age ranges will be most affected? Will mortality stem from our immune response to the virus, from comorbid conditions, or from secondary bacterial infections?” We know very little at present about most of these critically important questions.

In the United States and at the WHO, significant progress in pandemic planning has been made at the level of strategic planning. In a sea change from the situation that existed prior to the 2009 pandemic, comprehensive websites including detailed information for health care workers and businesses, risk assessment tools, and guidelines for entities ranging from individuals to businesses to entire countries are now available.^{454,504} The US strategy takes three parts: preparedness and communication, surveillance and detection, and response and containment. Much of the governmental focus in the United States in the area of response and containment has been on stockpiling antivirals.⁵¹¹ This is appropriate as a stopgap measure to control the pace of viral spread²⁷¹

TABLE 178.3 Priorities for Pandemic Planning	
Surveillance	Wild birds, human-avian and human-swine interface, human-to-human transmission
Research	Virulence determinants, capacity to reassort with human strains, requirements for transmission, interactions with the immune system
Stockpiling antivirals	Capacity for early intervention before vaccine is available
Pandemic vaccines	Pre- and postpandemic vaccine strategies
Nonpharmaceutical interventions	Utility of hand hygiene, masks, social distancing strategies, and community-based interventions

Modified from McCullers JA. Preparing for the next influenza pandemic. *Pediatr Infect Dis J* 2008;27:S57-S59.

or protect key individuals, but is insufficient as a total solution because of cost, distribution, and effectiveness concerns.²⁰⁶ Unfortunately, the least expensive and most widely available agents, the adamantanes, are not effective against most H5N1 strains.^{179,299} The most popular choice for stockpiling, the NA inhibitor oseltamivir, has not been highly effective thus far in laboratory-confirmed cases of H5N1 infection,³⁹⁸ and resistance has been shown to develop in select treated cases.²⁵⁴ Strategies based on prophylaxis of contacts at the start of a pandemic to slow or limit the spread of the pandemic, buying time for development of a vaccine, may be the best option available.^{272,272} However, this strategy was ineffective during the 2009 pandemic because of delayed recognition of early cases.

Numerous pandemic or universal vaccine candidates are in pre-clinical or clinical development at present.^{97,201,400} Perhaps the most difficult obstacle to developing such a vaccine is that we will not know what strain or even subtype to make a vaccine against until the pandemic starts. Because of the long production timeline for influenza vaccines (6–10 months), it is unlikely that an effective, well-matched vaccine can be prepared before the first wave of the pandemic virus has circumnavigated the world. Thus, most of the emphasis for planning has to be on mitigation strategies such as antiviral use, or implementation of other measures broadly dubbed “nonpharmaceutical interventions.”^{226,288,447} This includes strategies to prevent or decrease the likelihood of both transmission and acquisition of virus by maintaining personal spacing and decreasing contact between individuals, practicing good hand hygiene, using masks when close contact cannot be avoided, and intervening at the community level by closing schools and discouraging gatherings.
